Abstract. Gallbladder cancer (GBC) is an uncommon malignancy that is highly aggressive in the advanced stages. However, it rarely metastasizes to the mandible. Numb chin syndrome (NCS) is a rare neurological manifestation associated with various underlying causes, including occult primary cancers and distant metastases. It is often considered to be a significant indicator of malignancy, and thorough investigation is essential in the presence of unclear etiology. The current study reported on the case of a 69-year-old Japanese woman who presented with numbness and mild pain in the lower lip and chin area for three months. No other systemic symptoms were observed. Immunocytochemical examination revealed the presence of an adenocarcinoma and TNM staging as per the Union for International Cancer Control and the American Joint Committee on Cancer guidelines confirmed stage IVb GBC. Comprehensive full-body positron emission tomography-computed tomography examination using

¹⁸F-fluoro-2-deoxy-D-glucose revealed additional bone and soft-tissue metastases. Palliative chemotherapy and radiation treatment were initiated based on the advanced stage of disease at the time of diagnosis. However, the patient succumbed to multiple organ failure six months later. The simultaneous occurrence of GBC, mandibular metastasis and NCS is rare and associated with poor prognosis. Despite the widespread nature of the disease, it can often manifest as non-specific oral symptoms without any systemic indications. The current study emphasizes the critical importance of timely confirmatory testing for accurate diagnosis and initiation of appropriate management for such complex conditions.

Introduction

In 2020, ~115,949 new cases of gallbladder cancer (GBC) were reported globally (1). GBC is a rare, aggressive and complex disease that mostly originates from the organ's epithelial cells (2,3). The highest incidence rates were observed among indigenous populations in South America, northern India and East Asia, as well as individuals aged 70-74 years (1-3). GBC, while uncommon overall, ranks as the 23rd most prevalent cancer globally. Among men, it holds the same position, while among women, it occupies the 20th space (2). Matsuda and Saika (4) report that in Japan, the incidence of GBC and biliary tract cancers (classified under the International Classification of Diseases version 10 category C23-C24) is 11,641 cases in males and 10,699 in females. The age-standardized incidence rates for these cancers are 5.9 per 100,000 male and 3.6 per 100,000 female individuals. Furthermore, these rates vary with age and geographical region, with the highest incidence being observed in individuals in the seventh and eighth decades of life, as well as those living in the northern regions of the country (5).

The etiology of GBC involves a complex interplay of numerous genetic, epigenetic and environmental risk factors, including gallstones, chronic inflammation, congenital anomalies, obesity and genetic/molecular alterations (6).

Key words: numb chin syndrome, metastatic gallbladder cancer, mandibular osteomyelitis, oral metastases, pathological fracture, case report

Comprehensive diagnosis and management of GBC includes thorough clinical evaluation, imaging, histopathological examination, staging and development of individualized treatment strategies that adopt a multidisciplinary approach (7). Despite significant advancements in treatment, the overall survival rates of GBC remain relatively low, predominantly due to delayed diagnosis, as early-stage lesions that are confined to the gall bladder and have not invaded adjacent structures or metastasized are typically associated with better prognosis (8).

Metastatic tumors in the oral region account for ~1% of all oral malignancies (9). However, while several studies have reported metastasis of primary breast, lung and kidney tumors to this region, there is limited evidence of the spread of GBC (10). Metastasis typically involves a complex series of steps wherein the cancer cells first invade the blood and/or lymphatic vessels before spreading to distant sites, such as the mandible (11).

Numb chin syndrome (NCS) is a rare, sensory neuropathy that affects the mental nerve, leading to unilateral or bilateral altered sensations, decreased sensitivity or absence of pain in the chin and surrounding regions. Perez *et al* (12) recently reported that NCS was associated with various local and systemic etiological factors (summarized in Table I), including primary mandibular tumors or distant metastases of other cancers (13-33). It is commonly observed in association with metastasized breast cancer (32%), lymphoma and leukemia (24%), or prostate cancer (9%), and less frequently observed in association with lung cancer, myeloma, bone cancer, soft-tissue cancer, colon cancer, kidney cancer, adenoid cystic carcinoma, melanoma, skin cancer and digestive cancers such as GBC (13-19). The exact mechanisms underlying NCS remain unclear, although certain studies hypothesized nerve compression or damage as a consequence of tumor infiltration and invasion into the mandibular canal and bone (13,34). Accurate diagnosis of the cause of NCS can be challenging, highlighting the importance of prompt confirmatory testing and timely treatment.

The current study focuses on a rare case of GBC metastasis to the mandible accompanied by NCS. This combination posed significant diagnostic challenges due to its similarity with other mandibular pathologies, and the current case report aims to emphasize the critical significance of timely confirmatory testing to ensure accurate diagnosis and effective management of this complex condition.

Materials and methods

Literature search strategy. Multiple databases, including PubMed (<https://pubmed.ncbi.nlm.nih.gov/>), Embase (<https://www.embase.com/>) and Web of Science (<https://www.webofscience.com/>), were extensively searched for studies examining patients with metastatic GBC or extra biliary tract cancer. The search terms used included 'gallbladder cancer', 'carcinoma of the gallbladder', 'metastatic gallbladder cancer', 'carcinoma to the mandible', 'metastatic gallbladder cancer to the oral and maxillofacial region', 'head and neck metastatic gallbladder cancer' and 'numb chin syndrome'. The subsequent literature review primarily focused on studies published in English, although those published in other languages were also evaluated for relevance and new information. No restrictions

regarding the publication date were applied, with the earliest study being published in 1961, and the findings of the literature search were summarized in Table II (35-43).

Case report. In April 2015, a 69-year-old Japanese female patient presented at the Oral and Maxillofacial Surgery Department of the Red Cross Hospital (Naha, Japan) with the chief complaint of a tingling (numbness) sensation on the right side of the chin and lower lip and mild pain during molar occlusion since February 2015. The patient had been referred by a dentist for further investigation and management of suspected periodontitis in the right mandibular second premolar region and/or right mandibular osteomyelitis. The patient had previously undergone dental prosthetic treatment, including a partial denture for a missing right mandibular first molar. In addition, the patient had a history of chronic, well-controlled hypertension and type 2 diabetes mellitus and an unremarkable family history.

Upon examination, the patient was indicated to be well-nourished and in good condition, and exhibited no signs of pallor, jaundice, cyanosis, clubbing or localized/generalized lymphadenopathy. Although systemic examination yielded inconclusive results, the patient declined further exploration due to a lack of clear indications. Local examination revealed normal facial symmetry and a lack of sensation on the right side of the mandible extending from the labial commissure of the mouth to the midline of the inferior labium, including the vermilion and anterior chin. This area is innervated by the mental nerve (Fig. 1). Intraoral examination showed mild gingival erythema extending from the right mandibular second premolar to the right mandibular second molar. No obvious abnormalities were observed in the right mandibular first molar region.

Further investigation included orthopantomogram (OPG), contrast-enhanced computed tomography (CT), contrast-enhanced magnetic resonance imaging (MRI) using the short-tau inversion recovery (STIR)-PROPELLER technique, as well as hematological, cytology and histopathological examinations. OPG and MRI T2-weighted/STIR imaging showed alveolar bone resorption and high signal intensity between the right mandibular second premolar and second molar, indicating aggressive inflammation (Figs. 2 and 3). CT imaging showed mild osteolytic changes around the root of the right mandibular second premolar (Fig. 4), while hematological examination showed normal complete blood count levels. However, the C-reactive protein (CRP) and carbohydrate antigen 19-9 (CA 19-9; sialyl-Lewis^A) levels were elevated at 2.71 (reference value: 0-0.5) mg/dl and 1161.99 (reference value: 0-37) U/ml, respectively. Although non-specific, the erythrocyte sedimentation rate test was an unremarkable at 28 mm/h (local reference range for the 60-69-year age category, 2-40 mm/h; Westergren method). The patient's electrolyte levels, liver and renal function, complement titer, thyroid function, autoantibody levels, cytomegalovirus antibody levels and Epstein-Barr virus antibody levels were all normal. Core needle cytology examination indicated an inflammatory process (data not shown), prompting an initial diagnosis of right mandibular osteomyelitis with a strong suspicion of cancer. As the patient's medical history included tooth extraction, prosthetic treatment and absence of a prior diagnosis of

cancer, the possibility of tumorous lesions could not be ruled out based on CT and MRI images of the head and neck only. However, the patient declined additional comprehensive

investigations including histopathology and a full-body evaluation using positron emission tomography (PET)-CT. The right mandibular second premolar was subsequently extracted, and

Figure 1. Photograph of the lower face of the 69-year-old female Japanese patient. The blue dotted area is innervated by the mental nerve and exhibited poor sensory perception.

Figure 2. Orthopantomograph. The red arrow indicates mild resorption of the periapical alveolar bone extending from the right mandibular second premolar to the right mandibular second molar.

mandible biopsy cytology examination suggested osteomyelitis (Fig. S1). Treatment with broad-spectrum antibiotics alleviated the numbness. However, an immediate evaluation for extraoral cancer was strongly recommended. The patient returned with a chief complaint of swelling and pain in the right mandible two months later and underwent extraction of the right mandibular second molar. Biopsy cytology examination suggested mandibular osteomyelitis again and the patient was advised to continue with anti-inflammatory and antibacterial treatment. However, the patient's symptoms persisted despite ongoing treatment, and she developed difficulty in mouth opening and further lip paresthesia 1 month later. At this point, the patient also developed severe pain in the right upper arm, and an orthopedic surgeon was consulted. Radiographic examination showed a pathological fracture (Fig. 5) due to suspected bone metastasis. Consequently, the patient was referred to the Department of Internal Medicine of the University of the Ryukyus Hospital (Nishihara, Japan) for extended investigation of the primary tumor. Contrast-enhanced CT imaging of the thorax and abdomen and full-body PET-CT imaging showed features suggestive of GBC with lymph node, bone, lung and liver metastasis (Fig. 6A and B). The lung and liver lesions were strongly suspected to be metastatic tumors based on CT imaging and the absence of any evidence of viral hepatitis.

Figure 3. CT scan. Minor resorptive bone changes observed around the root of the right mandibular second premolar (arrow).

Figure 4. MRI coronal T2-weighted/short-tau inversion recovery-PROPELLER technique image showing a high signal intensity area between the right mandibular premolar and molar, suggesting aggressive inflammation and osteomyelitis of the right mandible.

Intraoral biopsy of the jaw tumor was repeated and histopathological analysis including hematoxylin and eosin (HE) staining and immunohistochemical (IHC) examination was carried out by at least two pathologists at the pathology department of the University of the Ryukyus Hospital (Nishihara, Japan). The specimens were cut into 4- μ m-thick sections, fixed with 96% ethanol and immersed in a 10% formalin solution at 4°C for 24 h. Thereafter, hematoxylin staining was performed for 30 sec and the samples were rinsed with water at 4°C for 5 min and then counterstained with eosin Y at 4°C for 15 sec. The samples then underwent dehydration with 96 and 99.8% ethanol and xylene fixation, before being sealed with coverslips using mounting medium. Diagnostic images were captured using a Nikon Eclipse Ci microscope equipped with a Nikon DS-Fi3 camera with a x4 objective (Nikon Corporation). IHC examination was

Figure 5. Radiographic examination of the right upper arm showing a pathological fracture caused by bone infiltration of the tumor.

conducted using the streptavidin-peroxidase technique at room temperature. The 4- μ m-thick sections were rinsed with PBS before being subjected to 10 min of pepsase (1:1,000 dilution; Sigma-Aldrich; Merck KGaA) processing for antigen retrieval. They were then incubated in methanol and 3% hydrogen peroxide to deactivate endogenous peroxidases, blocked with PBS containing 0.5% Tween-20 (Sigma-Aldrich; Merck KGaA) and 3% bovine serum albumin (Sigma-Aldrich; Merck KGaA) for 1 h at room temperature, and then incubated with primary antibodies, including rabbit anti-cytokeratin (CK)7 (1:1,600 dilution; cat. no. ab199718; Abcam) and rabbit anti-CK20 (1:200; cat. no. ab64090; Abcam), overnight at 4°C. After three washes with PBS, a secondary antibody, goat anti-rabbit IgG H&L (HRP; 1:500 dilution; cat. no. ab97051; Abcam) was introduced along with fresh diaminobenzidine as the substrate for 1 h at room temperature. Negative controls were prepared using PBS instead of the primary antibody, and the Philips IntelliSite Pathology Solution (Philips Medical Systems) was used for image acquisition (data not shown). The histopathological analysis showed the presence of tumor cells with strongly atypical nuclei of unequal size, eosinophilic sporangia and an indistinct cord-like structure (Fig. 7) in the mandibular gingiva. Immunostaining revealed diffuse positivity for CK7 (Fig. 8A), partial positivity for CK20 (Fig. 8B) and negativity for hepatocyte-specific antigen and p40 (results not shown). The staining pattern was negative for hepatocellular

and squamous cell carcinomas, indicating GBC metastasis (Fig. 8).

A diagnosis of stage IVb (T4N3M1) GBC, as per the American Joint Committee on Cancer classification (44), was made and the patient was admitted to the Red Cross Hospital (Naha, Japan) in October 2015 for palliative treatment due to the advanced stage of cancer and presence of multiple

metastases. Combination intravenous chemotherapy with 1,000 mg gemcitabine (Eli Lilly and Co.) and 32.5 mg cisplatin (Teva Pharmaceutical Industries Ltd.) was administered along with a pain control regimen consisting of a subcutaneous injection of 12 mg denosumab (Amgen Inc.) and a combination of narcotic drugs. Furthermore, 27 Gy irradiation was applied to the right upper arm. Despite treatment, the patient's symptoms did not improve significantly and she succumbed to multiple organ failure in November 2015.

Discussion

Extraoral metastatic tumors are an exceptionally rare occurrence, accounting for only 1% of all oral malignancies (9,45). Primary lesions that may metastasize to the oral cavity include lung, kidney, liver and prostate neoplasms in men and breast, genital, kidney and colorectal neoplasms in women (10). GBC typically spreads through direct extension to the liver and adjacent organs within the gastrointestinal tract before involving the regional lymph nodes. Instances of metastatic GBC in distant organs have been documented, but its spread to the oral cavity remains conspicuously rare, with only a small number of cases observed to date (Table II).

The determinants of oral cavity metastasis include the nature of the primary tumor, lesion stage, presence of lymphatic and vascular channel invasion, regional lymph node involvement, tumor size, histological characteristics of the lesion, patient's immune status, genetic factors and the micro-environments of the tumor and distant site. Delay in diagnosis and treatment of the primary tumor may substantially increase the risk of metastasis, with the mandible being particularly vulnerable in the oral region due to its rich blood supply (46). Metastasis of GBC to the mandible involves a complex interplay of molecular mechanisms, such as epithelial-mesenchymal transition, angiogenesis, lymphatic and hematogenous dissemination, extracellular matrix remodeling, evasion of immune surveillance, adaptation to the distinct mandibular microenvironment and concurrent genetic mutations and alterations that may potentially influence lesion aggressiveness and its capacity to infiltrate adjacent tissues and spread to distant sites (47-51).

Oral cavity metastasis typically has a poor prognosis, with most patients dying within one year of diagnosis (35-43). The prognosis depends on the treatment of the oral cavity lesion, as well as adequate control of the primary tumor and metastasis (advanced disease) (35-43,52). In the present case, the patient was diagnosed with extensive GBC metastasis throughout the body, and the patient's condition had deteriorated significantly by the time of admission to the Department of Internal Medicine of the University of the Ryukyus Hospital (Nishihara, Japan). Consequently, the patient succumbed to the disease 7 months after the initial diagnosis.

The present study was limited by the absence of initial intraoral photographs and images documenting the oral treatment process. These images could have provided additional insight into the progression and response of the oral metastasis to treatment, thereby enriching the visual documentation of this rare case. However, it should be emphasized that their absence does not diminish the clinical and diagnostic relevance of the findings presented. The absence of negative control IHC

images, excluded from the analysis, could have potentially aided in the validation of the staining specificity and enhanced the interpretive accuracy for the reader. However, this potential limitation is mitigated by the comprehensive diagnostic approach employed in the present retrospective case report. To further uphold and enhance the scientific integrity of the reported findings, improved access to and inclusion of relevant investigation control data/images will be a key focus in our future studies.

A diagnosis of metastatic tumors in the oral and maxillo-facial region may be made if the presence of a primary tumor located outside this region has been histologically and clinically confirmed, a clear distinction and absence of invasion between the primary tumor and metastases is observed and the patient has no history of a previous primary lesion in the same region (9,52). In the present study, the patient met all of these criteria, leading to the diagnosis of a metastatic tumor originating from GBC. GBC is a highly aggressive cancer that often spreads to nearby organs. Distant metastasis to the lungs, chest cavity (9.4%), skeletal system (2.4%) and the brain has been reported, although there is limited evidence of metastasis to the oral region (37,53-56).

NCS, first described by Calverley in 1963 and characterized by hypoesthesia limited to the lower lip and mental region due to mental nerve palsy (34), is often observed in association with metastatic malignancies of the mandible or infiltration of hematopoietic tumors such as lymphomas (13). While malignant lymphomas commonly present with NCS as the first symptom, followed by leukemia, gastric cancer, lung cancer and others, metastatic GBC with NCS as the initial symptom is a rare occurrence (34). In the current study, OPG showed no significant abnormalities, and a definitive diagnosis was made after histopathological confirmation. OPG alone may be insufficient during the early stages of invasion. CT and MRI scans may be used for lesion identification, although differentiation from mandibular osteomyelitis may be challenging. The patient's lack of relevant surgical and/or cancer history and initial failure to fully explore the condition due to personal reasons may have contributed to delays in diagnosis. As the majority of patients exhibiting malignancies with NCS as the initial symptom have a poor prognosis, it is presumed that the cancer had already progressed significantly at the time of onset of symptoms (10).

Distinguishing metastatic malignant tumors arising in the jawbone from mandibular osteomyelitis may be challenging due to the similarities in their clinical and radiological features, with both conditions presenting with lower lip hypoesthesia and mandibular bone resorption (57,58). Hariya *et al* (57) categorized the morphology of bone resorption into point, mass and infiltrative fractures, and found that both malignant tumors of the jawbone and mandibular osteomyelitis were associated with a higher degree of bone resorption. Intra-mandibular malignant tumors with infiltrative bone resorption typically present as a worm-eaten pattern, while mandibular osteomyelitis presents as point-like and massive resorption of cortical bone without infiltrative bone resorption on CT images. Cortical bone swelling is typically observed in intra-mandibular malignancies and is absent in patients with mandibular osteomyelitis. Furthermore, although periosteal reactions and osteosclerotic features are frequently seen in patients with mandibular osteomyelitis, they

have also been reported in association with intra-mandibular malignant tumors (57,58). In the present study, initial CT images revealed no resorption or mass formation in the lateral cortical bone of the mandible. However, elevated levels of CRP, CA19-9 and ESR were observed, and a history of tooth extraction with subsequent denture placement, coupled with pain in the region of the right mandibular second premolar, suggested potential mandibular osteomyelitis or malignancy. Consequently, biopsy cytology was undertaken following the premolar extraction, leading to a diagnosis of mandibular osteomyelitis. Diagnosis was delayed due to several factors, including the absence of a significant surgical or cancer history of the patient and the typically occult presentation of GBC (1,2). Although core needle biopsy provides a valuable tool for preliminary assessment of tumorous lesions and treatment guidance, its limitations, particularly regarding the potential for inadequate tissue sampling and preservation, as well as the ability to accurately assess certain biomarkers by IHC testing, should be recognized to avoid negatively impacting the diagnostic process (59).

Omics analyses, including metabolomics, transcriptomics and proteomics studies, were not conducted in this study due to the rapid deterioration of the patient's condition and her reluctance to undergo comprehensive assessments. Furthermore, attempts to conduct posthumous analyses were hindered by the absence of stored blood samples from the patient. Omics analyses, employing liquid biopsies, chromatographic separation, mass spectrometry and molecular biology techniques, show great promise for cancer diagnosis and prognosis (60). However, challenges persist, as identified by Wang *et al* (60), including variability in quantification and detection depending on the metabolomics approach-targeted or untargeted- and the choice of instruments. In addition, the considerable heterogeneity of metabolites among different cancer types, influenced by numerous factors, adds to these challenges (60). Therefore, while these analyses could have provided deeper insight into the molecular underpinnings of the metastatic process, their absence does not detract from the clinical and histopathological findings that form the basis of the present case report. This highlights the importance of considering the preservation of biological samples in future cases for advanced molecular studies.

The current study emphasizes the critical need for timely diagnosis and multimodal therapy in patients presenting with initial vague symptoms to improve outcomes in aggressive metastatic malignancies such as GBC.

In conclusion, the present case report underscores the rarity of GBC metastasizing to the oral region and presenting as NCS. It highlights the critical need for prompt, thorough evaluation of neurological symptoms to detect hidden malignancies and the importance of differentiating bony metastases from conditions such as osteomyelitis through comprehensive diagnostic methods. The study also emphasizes the value of multidisciplinary collaboration for the timely diagnosis and treatment of complex metastatic diseases. In addition, it points to the potential of emerging technologies such as metabolomics in cancer research, underscoring the necessity for swift confirmatory tests and accurate diagnoses in managing metastatic cancers.
