Abstract. Neuregulin 1 (NGR1) and survivin have been shown to be neuroprotective. However, the link between their expression and aspirin in the treatment of cerebral ischemia remains unclear. Here, we investigated the effect of aspirin on NGR1 and survivin expression after focal cerebral ischemia/reperfusion in rats. Sprague Dawley rats were randomly divided into an aspirin treatment group (n=40) and a control group (n=40). Each group was further divided into five subgroups according to the time after reperfusion. A middle cerebral artery model was established by an occlusion suture. At 24 h, 3, 5 and 7 days after reperfusion, the Bederson neurological deficit scores were 1.47 ± 0.11 , 1.22 ± 0.08 , 0.85 ± 0.15 and 0.59 ± 0.12 in the treatment group, and 1.87 ± 0.18 , 1.45 ± 0.14 , 1.05 ± 0.08 and 0.75 ± 0.15 in the control group, respectively, indicating a significant difference at each time point ($P < 0.05$). In the infarct center, the number of NGR1- and survivin-positive cells reached the maximum at 6 h and decreased gradually to a minimum at 7 days, while in the peri-infarct area, the number was few at 6 h, peaked at 3 days and then was reduced gradually with significant differences between the two time points ($P < 0.05$). There were more NGR1- and survivin-positive cells in the treatment group compared to the control group ($P < 0.05$). In conclusion, the neuroprotective effect of aspirin is at least partly mediated by the upregulation of NGR1 and survivin expression after ischemia.

Introduction

Neuregulin 1 (NGR1) is a signaling protein which plays an important role in the nervous system development. It is mainly expressed in neurons, glial cells and organs, such as the heart, liver, stomach, lung, kidney and spleen. Moreover, NGR1 is implicated in numerous nervous system diseases. In models of cerebral ischemia, exogenous NGR1 inhibits neuronal apoptosis and reduces the volume of cerebral infarction (1-6). Survivin is a well-known anti-apoptotic protein that inhibits

the activities of caspase-3 and caspase-7. Only recently has the role of survivin in cerebral ischemia become appreciated (7). Aspirin has neuroprotective effects, including the inhibition of apoptosis of ischemic brain cells (8,9). However, the link between NGR1 and survivin expression and aspirin in the treatment of cerebral ischemia remains unclear. Here, we investigated the effect of aspirin on the expression patterns of NGR1 and survivin after focal cerebral ischemia/reperfusion in rats to further explore the neuroprotective mechanism of aspirin.

Materials and methods

Animals and groups. A total of 80 healthy male Sprague Dawley rats (weight 240-280 g) were provided by the Medical Animal Laboratory, Shenyang Military General Hospital. Animals were fasted for 12 h prior to surgery with water offered *ad libitum*. The rats were randomly divided into a treatment group (aspirin, n=40) and a control group (L-lysine, n=40). Each group was further divided into five equal subgroups according to the time since reperfusion (6 h, 24 h, 3, 5 and 7 days, n=8 in each group). Aspirin powder was provided by the Pharmaceutical Factory of Shenyang Pharmaceutical University, and diluted with L-lysine before use.

Establishing the cerebral ischemia/reperfusion (CI/RP) model. Cerebral ischemia was established with an occlusion suture as previously described (10,11). Two hours after the induction of cerebral ischemia, the suture was pulled back slowly ~2 mm for reperfusion. Aspirin powder (80 mg/kg body weight) dissolved in 1.5 ml of 10% L-lysine saline solution was injected intraperitoneally at the time of reperfusion and once each morning thereafter. Brain samples were obtained at 6 h, 24 h, 3, 5 and 7 days after reperfusion. In the control group, intraperitoneal infusion of 1.5 ml of 10% L-lysine solution was administered at the same time points, and brain samples were obtained as in the treatment group. No sham-operated group was set since sham operation on cervical vessels does not cause cerebral infarction in the supplied area. Supplementary rats were available according to a protocol of randomization and grouping when rats were excluded or died during the experiment. The evaluation of limb function was carried out according to the Bederson scoring system (12) every day after the CI/RP surgery to assess the recovery of neurological function. The scoring formula was as follows: 0, without any neurologic deficit; 1, dysfunction of left forelimb extension; 2, walking towards the left; 3, circling

towards the left; 4, were unable to walk or in a coma. Rats with scores of 1-3 were assumed to be successful CI/RP models and others were excluded from the study.

Immunohistochemical analysis. Immunohistochemical analysis was performed as described previously (13). At each experimental time point, after intraperitoneal anesthesia with an overdose of chloral hydrate (10%), the thoracic cavity was immediately opened to expose the heart. Perfusion then proceeded rapidly with 200 ml isotonic saline and 200 ml 4% paraformaldehyde in PBS injected into the left ventricle. The brain was extracted after decapitation and fixed in 4% paraformaldehyde for 24 h. Brain tissues were incised along the coronal plane, and then conventionally dehydrated and embedded in paraffin. Serial sections were cut at a thickness of 4 mm, and dried at 37°C in an incubator overnight. Immunohistochemical staining was performed using S-P immunohistochemical and diaminobenzidine (DAB) kits (Fujian Maixin Biological, Fujian, China). NGR1 polyclonal antibody (sc-348) was from

Santa Cruz Company, USA. Positive cells showed as brown particles in the cytoplasm or nucleus under a light microscope. Five different high power fields (10 \times 40) were randomly selected blindly in positive cell areas (the temporal parietal cortex was selected in the penumbra area and the temporal parietal subcortex was selected in the infarct center), and the number of positive cells in each visual field was counted (14).

Statistical analyses. Statistical Package for the Social Sciences (SPSS) 12 software was used for statistical analyses. Data are represented as the means \pm standard deviation (SD). Variance analysis and the t-test were used for tests of significance. A P-value <0.05 was considered to denote statistical significance.

Results

After induction of CI/RP, neurological deficit was observed in both the treatment and control groups, and the main manifestations were as follows: adduction of the contralateral forelimb;

Figure 1. Intracerebral NGR1 expression at different sites after CI/RP in rats. Brown staining represents positive NGR1 expression. (A) Infarct center in the treatment group (6 h). (B) Infarct center in the control group (6 h). (C) Infarct center in the treatment group (24 h). (D) Infarct center in the control group (24 h). (E) Infarct center in the treatment group (3 days). (F) Infarct center in the control group (3 days). (G) Peri-infarct area (cortical pyramidal layer) in the treatment group (3 days). (H) Peri-infarct area (cortical pyramidal layer) in the control group (3 days). (I) Peri-infarct area (cortical pyramidal layer) in the treatment group (5 days). internal rotation of the shoulder; the left forelimb could not straighten, or it was held close to the chest while lifting the tail; sinistral circular motion; dumping; and decreased muscle tension while walking. At 6 h after reperfusion, neurological deficit scores were assessed again in the two groups, compared and examined by t-test. No significant difference was found between the two groups ($P>0.05$). Twenty-four hours after CI/RP surgery, neurological function was restored gradually in both the treatment and control groups, although a better recovery was found in the treatment group. There were statistically significant differences in Bederson scores between the two groups at each time point after CI/RP ($P<0.05$; Table I).

Figure 2. Survivin expression in different infarct areas in CI/RP rats. Brown staining represents positive survivin expression. (A) Infarct center in the treatment group (6 h). (B) Infarct center in the control group (6 h). (C) Infarct center in the treatment group (3 days). (D) Infarct center in the control group (3 days). Survivin expression was also detected in small vascular endothelial cells (indicated by arrow). (E) Peri-infarct area (cortical pyramidal layer) in the treatment group (3 days). (F) Peri-infarct area (cortical pyramidal layer) in the control group (3 days). (G) Peri-infarct area (cortical pyramidal layer) in the treatment group (5 days). (H) Peri-infarct area (cortical pyramidal layer) in the control group (5 days). Magnification, $\times 400$.

After CI/RP, NGR1 expression was detected by immunohistochemistry in rat brain tissues in both the treatment and control groups. NGR1 was mainly expressed in the nucleus and cytoplasm of neurons in the infarct side. In the infarct center, NGR1 was expressed strongly 6 h after CI/RP, and the number of NGR1-positive cells was at a maximum at 6 h and decreased gradually. In the peri-infarct area, the number of NGR1-positive cells was small at 6 h, peaked at 3 days and then decreased gradually. Compared to the control group, more NGR1-positive cells were detected in the treatment group at each time point, with significant differences between both time points ($P<0.05$; Table II and Fig. 1).

The expression pattern of survivin was similar to that of NGR1 after CI/RP and, also, it was mainly expressed in the nucleus and cytoplasm of neurons in the infarct side. In addition, survivin expression was found in small vascular endothelial cells 3 days after CI/RP. In the infarct center, survivin was expressed strongly 6 h after CI/RP, and the number of survivin-positive cells was maximal at 6 h and decreased gradually. In the peri-infarct area, the number of survivin-positive cells was small at 6 h, peaked at 3 days and

decreased gradually. Compared to the control group, more survivin-positive cells were detected in the treatment group at each time point, with significant differences between the two time points ($P < 0.05$; Table III and Fig. 2).

Discussion

Emerging evidence suggests the potential neuroprotective role of NGR1 in cerebral ischemia. Increased NGR1 expression has been found in neurons of ischemic penumbra, although it is not expressed in astrocytes or microglia cells (15). In addition, injection of exogenous NGR1 into the brain or carotid artery reduces significantly the volume of the infarction and the number of TUNEL-positive and caspase-3-positive cells (1-6). Survivin is the strongest apoptosis inhibitory protein known, and it directly or indirectly inhibits the caspase-dependent or -independent apoptosis pathways (16).

Few reports have addressed the expression patterns of NGR1 and survivin after cerebral ischemia with exogenous stimulation (including administration of drugs). In the present study, the expression patterns of NGR1 and survivin in brain tissues after CI/RP alone, or in combination with aspirin administration, were examined by immunohistochemistry. The results demonstrated that NGR1 and survivin were mainly expressed in the nucleus and cytoplasm of neurons in the infarct hemisphere after CI/RP, transiting from the infarct center to the peri-infarct area. In the infarct center, NGR1 and survivin were expressed most significantly 6 h after CI/RP, and reached a peak after 3 days in the peri-infarct area. With aspirin treatment, the number of survivin- and NGR1-positive cells increased, but the time of peak expression did not change. In the early stage of CI/RP (within 6 h post-CI/RP), the infarct center was severely ischemic without complete necrosis in most of the neurons, therefore NGR1 and survivin expression remained high. However, the peri-infarct area was only mildly ischemic, and so there were only a few NGR1- and survivin-positive cells. As time passed (after 3 days), massive necrosis of neurons was found in the infarct center, and the expression of NGR1 and survivin subsided gradually. However, edema and ischemia in the peri-infarct area became aggravated, and the number of NGR1- and survivin-positive cells increased. At 7 days, NGR1- and survivin-positive cells were fewer, which may be related to the increased necrosis in the peri-infarct area and the restoration of cerebral blood supply. Taken together, our data suggest that ischemia is a strong stimulus to induce the expression of endogenous NGR1 and survivin. NGR1 and survivin expression may be further upregulated by exogenous aspirin. NGR1 and survivin may play neuroprotective roles through the inhibition of apoptosis, providing a mechanism by which aspirin exhibits its neuroprotective effects.

Conway *et al* (7) reported that survivin was also expressed in cerebral pia mater and small blood vessels. Our experiment also confirmed that survivin is expressed in a portion of the vascular endothelial cell infract center and peri-infarct area, but NGR1 was not expressed in these areas. These data indicate that survivin promotes angiogenesis (7). Indeed, survivin is upregulated by VEGF and plays an anti-apoptosis role in the process of angiogenesis (17). Plate *et al* (18) reported that after middle cerebral artery occlusion, the mRNA expression of vascular endothelial growth factor (VEGF) was detected in gliocytes and macrophages in the

perivascular ischemic penumbra and reached a peak after 2 days (18), which appropriately coincides with post-ischemic angiogenesis in the infarct center (19). Although VEGF may facilitate the leakage of capillary blood and destroy the blood-brain barrier to aggravate brain edema, its effect on angiogenesis may be beneficial to long-term recuperation (20). Therefore, we propose that the concomitant upregulation of VEGF and survivin may help maintain a balance and promote maximal neuroprotective effects against cerebral ischemia/reperfusion.
