**Abstract.** The aim of the present study was to investigate the electrophysiological properties of transient receptor potential melastatin 7 (TRPM7) channels in the cell membranes of cardiac fibroblasts (CFs). CFs obtained from Sprague-Dawley rats were treated with six different concentrations of angiotensin (Ang) II for 12 h. The optimum concentration of Ang II for inducing fibrosis was selected by measuring collagen protein expression levels at each concentration. The optimum concentration of Ang II was then used to treat the CFs at five different time-points, and the TRPM7 current across the CF membranes was recorded along with the collagen protein levels in each group. The optimum Ang II concentration for inducing fibrosis was found to be 1 nmol/l; when it was administered to CFs at 0, 6, 12, 24 and 48 h, the protein expression levels of TRPM7 and collagen III initially increased, reaching maximum levels at 12 h, and then decreased. This result positively correlated with the TRPM7 current levels on either side of the CF membranes: The TRPM7 current under the effect of the optimal Ang II concentration for inducing fibrosis was initially increased and then later decreased. This is one of the key mechanisms by which Ang II mediates the proliferation and apoptosis of CFs. This knowledge may be used to identify treatments for the prevention of cardiac fibrosis.

## Introduction

Cardiovascular diseases have become the leading cause of disability and mortality worldwide (1). Cardiac fibrosis is an important pathological and physiological response to various diseases (at the middle and end stages), including heart failure,

hypertrophic cardiomyopathy, myocardial infarction and malignant arrhythmias, and it is a challenge in current clinical therapy (1). A growing body of evidence indicates that cardiac fibroblasts (CFs) are the main cells responsible for the cardiac fibrosis process. Under the impact of a variety of cell stimulating factors, CFs promote an increasing influx of external ions. This leads to pathologic hyperplasia and pathological differentiation, the formation of cellular matrix-like collagen and the initiation of the tissue fibrosis process. Therefore, the identification of methods to enable early intervention in the function of CFs, in order to block the onset and delay the development of cardiac fibrosis, has become a key issue for study in recent decades (2,3).

A type of Ca<sup>2+</sup>-permeable channel with a high expression level of transient receptor potential melastatin 7 (TRPM7) has been found in the cell membranes of Sprague-Dawley (SD) rats (4,5). Previous studies have shown that TRPM7 is the only calcium channel expressed on the cell membrane of CFs (6) and that Ca<sup>2+</sup> signaling is closely associated with the initiation of fibrosis (7-9). These findings strongly suggest that TRPM7 may be the one of the most potent fibrosis factors, playing an important role in the molecular mechanism and pathological and physiological processes by which angiotensin II (Ang II) induces cardiac fibrosis. Therefore, it is hypothesized that TRPM7 is expressed at high levels when stimulated by Ang II. Ca<sup>2+</sup> signaling on the cell membrane of CFs may be mediated by the stimulatory effect of Ang II on TRPM7, causing collagen synthesis in the CFs to increase and leading to the fibrosis of cardiac interstitial tissue.

## Materials and methods

**Subjects.** SD rats (<3 days old) were purchased from Wuhan University Center for Animal Experiment/Animal Biological Safety Level-3 Laboratory (Wuhan, China). The study was approved by the Medical Ethics Committee of Renmin Hospital of Wuhan University.

**Cell culture.** The tissue method of Runnels *et al* (10) was adopted to separate and collect the rat CFs. Following resuspension in the culture solution [Dulbecco's modified Eagle's medium (DMEM)-F12 (Invitrogen Life Technologies, Carlsbad, CA, USA) supplemented with 10% fetal bovine serum (Santa Cruz Biotechnology, Inc., Dallas, TX, USA)], CFs were collected using the method of differential sedimentation and inoculated in

a culture dish. The cells were then synchronized by the starvation method in fetal bovine serum-free medium and placed in an incubator for subculture at 37°C and 5% CO<sub>2</sub>. The culture solution (containing mycillin and DMEM-F-12) was replaced once every 36 h. When the cell density was ≥90%, subculture was conducted by digesting cells with 0.25% trypsin and 0.5 mM EDTA. One agar plate was retained for the Ang II treatment group and the establishment of the normal control group.

#### *Cell interventions*

*Determination of the concentration of Ang II having the optimal fibrosis-inducing effect.* i) Treatment. The cultured CFs were separated into six groups, and DMEM culture solution (containing 10% fetal calf serum) was added along with 0, 1, 5, 10, 100 or 1,000 nmol/l Ang II. After 12 h (37°C), the expression levels of collagen I and collagen III proteins in each group were measured by western blotting and the group in which the concentration of Ang II had the greatest inducement effect for fibrosis was selected.

ii) Western blotting. Western blotting technology was adopted to evaluate the expression levels of collagen I and collagen III proteins in each group. The total cellular protein was extracted using a protein extraction kit in accordance with the manufacturer's instructions (Beyotime Institute of Biotechnology, Wuhan, China). The Bradford method was used to determine the protein concentration and equalize the protein concentrations in the samples of the different groups through adjustment. Electrophoresis by the SDS-PAGE technique was conducted based on 50 μg total protein/lane loading using electrophoresis equipment from Beijing Liuyi Instrument Factory (Beijing, China) and an SDS-PAGE gel preparation regulator from Wuhan Huge Biotechnology Co., Ltd. (Wuhan, China). Following the electrophoresis, the protein on the gel was transferred onto a polyvinylidene fluoride membrane. The gel was sealed with 5% skimmed milk powder [prepared with 0.5% Tris-buffered saline-Tween® (TBST)] at room temperature for 1 h. Rabbit polyclonal antibodies (1:500; Abcam, Cambridge, UK) against collagen I (cat. no. ab34710) and collagen III (cat. no. ab7778) were added following membrane rinsing and the membrane was incubated at 4°C overnight. The membrane was then incubated at room temperature for 30 min with goat anti-rabbit secondary antibody (1:3,000; cat. no. 074-1506; KPL, Inc., Gaithersburg, MD, USA) and washed three times (5 min each time) in a gyratory shaker at room temperature with TBST. Finally, fixation and color development with 3,3'-diaminobenzidine was conducted in a dark chamber. The conditions of exposure were adjusted based on the luminous intensity; the photographic film was scanned and filed; and AlphaEaseFC software (Alpha Innotech, San Leandro, CA, USA) was used to analyze the optical density of the blots.

*Recording the CF TRPM7 current.* i) Treatment. The cultured CFs were separated into five groups and treated for 0, 6, 12, 24 and 48 h with the optimal concentration of Ang II for inducing fibrosis. The TRPM7 current was determined for the five time-points as described below. In addition, the collagen and TRPM7 protein levels of the cells were determined using the previously described western blotting technique (anti-TRPM7; cat. no. ab109438; Abcam).

ii) Electrophysiological recording. The Axopatch 200B amplifier (Molecular Devices, LLC, Sunnyvale, CA, USA)

was used to record the whole-cell currents of the CFs. The ramp stimulus procedure was adopted with a stimulating voltage of 120±100 mV. The internal fluid (11) in the electrode included: 145 mmol/l cesium mesilate; 8 mmol/l sodium chloride; 10 mmol/l ethylene glycol tetra-acetic acid and 10 mmol/l hydroxyethylpiperazine ethane sulfonic acid (Sinopharm, Shanghai, China). The pH value was adjusted to 7.2 with sodium hydroxide solution. In certain experiments, 3 mmol/l Mg<sup>2+</sup> was added to the internal fluid (calculated by MaxChelator software; <http://maxchelator.stanford.edu>). The standard extracellular Tyrode solution was composed of 140 mmol/l sodium chloride, 5 mmol/l potassium chloride, 2 mmol/l calcium chloride, 20 mmol/l hydroxyethylpiperazine ethane sulfonic acid and 10 mmol/l glucose (Sinopharm). The pH value was adjusted to 7.4 with sodium hydroxide solution.

*Statistical analysis.* Data are presented as the mean ± standard deviation. Comparisons among groups were conducted with a Student's t-test on two independent samples. Statistical analysis was conducted using SPSS software (version 16.0; SPSS Inc., Chicago, IL, USA). P<0.05 was considered to indicate a statistically significant difference.

## **Results**

*Microscopic examination of the cultured CFs.* During microscopic examination, the CFs were observed to be elongated and spindle-like. They grew with a homogeneous distribution and arranged themselves into garland-like or roller forms. No cardiac impulse was observed (Fig. 1).

*Protein expression levels in CFs following treatment for 12 h with Ang II at various concentrations.* The expression levels of collagen I and collagen III in the CFs treated for 12 h with Ang II at different concentrations were determined by western blotting. Analysis of the results indicated that the expression levels of the two types of collagen induced by Ang II (1 nmol/l) were increased significantly compared with those in the other groups (P<0.05), which indicated that the concentration of Ang II having the best inducement effect for fibrosis was 1 nmol/l (Fig. 2).

*Protein expression levels of collagen I, collagen III and TRPM7 in CFs following treatment with Ang II for different time periods.* The protein expression levels of collagen III and TRPM7 gradually increased over time and reached a maximum when the duration of treatment was 12 h, gradually decreasing subsequently (Fig. 3). The TRPM7 current underwent corresponding changes (gradually increasing and then decreasing with time) and reached a maximum (8-fold higher than that of the 0 h group) when the duration of treatment was 12 h (as shown in Fig. 4). The protein expression level of collagen III was lower than that of the control group when the duration of intervention was 48 h (P<0.05). The protein expression level of TRPM7 remained higher than that of the control group (P<0.05). The protein expression level of collagen I reached a maximum when the duration of intervention was 24 h, and was significantly different from that in the other groups (P<0.05).

**Discussion**

TRPM7, belonging to the TRP superfamily, is an ion channel with dual channel and kinase activity (10). Its expression enables inward rectifier currents of  $Ca^{2+}$  to permeate cell membranes. The current amplitude rises with the consumption of  $Mg^{2+}$  inside the cell and is inhibited by other bivalent ions. TRPM7 is activated by protein kinase A and deactivated by phosphatidylinositol 4,5-bisphosphate (10). Previous studies have shown that TRPM7 plays a significant role in the growth and apoptosis of histiocytes, is activated by mechanical stress and is associated with vasodilation (12-14). It has been reported that the expression of TRPM7 by vascular smooth muscle cells is significantly upregulated when activated by transforming growth factor (TGF)- $\beta$ 1 and fluid flow (15). The expression of TRPM7 in CFs has previously been verified by immune cytochemistry (16). Two

characteristics of TRPM7 channels, specifically, that they are non-voltage-gated and have  $Ca^{2+}$  permeability, suggest

that they may have significant pathological and physiological functions in various cells, particularly in non-excitabile cells such as CFs.

Preliminary research suggested that the TRPM7 ion channel is the molecular basis of the TRPM currents observed in our previous studies (4,5). It also suggested that the resting membrane potential level of CFs is -25 mV, under which all voltage-gated channels are in the deactivation state. This further supports TRPM7 being the only channel for the inward flow of  $Ca^{2+}$  in CFs. Under the impact of endogenous and exogenous stimulating factors, TRPM7 channels would open, leading to a considerable flow of extracellular  $Ca^{2+}$  into the cell. This flow is likely to cause collagen synthesis to increase, leading to fibrosis. Furthermore, the considerable inward flow of  $Ca^{2+}$  would activate signaling pathways such as the mitogen-activated protein kinase (MAPK) and TGF- $\beta$ /Smad pathways, causing inflammation, apoptosis and cellular differentiation leading to an acceleration of fibrosis.

During one preliminary clinical study, it was found that the myocardial tissues of patients suffering from atrial fibrillation had a certain degree of fibrosis (17); another preliminary clinical study showed that in the myocardial tissues of patients suffering from atrial fibrillation due to rheumatic heart disease, the mRNA and protein expression levels of TRPM7 rose significantly compared with those of individuals with sinus rhythm (18). These studies suggest that under the impact of abnormal stimulation, such as an increased volume and pressure load, TRPM7, the only  $Ca^{2+}$  channel protein on CFs would be activated and its expression increased. This would increase the internal flow of extracellular  $Ca^{2+}$  to the cell to activate and launch biological signaling cascades leading to the pathological transfer, differentiation and secretion of a large quantity of extracellular matrix, finally giving rise to cardiac interstitial fibrosis.

The primary causes of fibrosis include the disequilibrium between pro-fibrogenic cell growth factors and anti-fibrogenic cell growth factors. Studies on myocardial fibrosis have gradually focused on cell growth factors, which include TGF, connective tissue growth factor, basic fibroblast growth factor and hepatocyte growth factor (8,19,20). Ang II, frequently researched in recent years, is the pro-fibrogenic cell growth factor (8). Ang II plays a significant role in the occurrence and development of organ fibrosis. Through protein quantification, the present study verified that the concentration of Ang II having the greatest inducement effect for fibrosis was 1 nmol/l. The results also showed that Ang II at various concentrations had different effects on the growth of CFs: the effect of Ang II on CFs was concentration-dependent. The effect on the growth of CFs decreased as the concentration continued to rise; this may be associated with an increase in the induction of apoptosis and necrosis of the cells. The protein expression levels of TRPM7 and collagen III obtained by treating CFs for 0, 6, 12, 24 and 48 h with the optimum concentration of Ang II increased at first and reached a maximum when the duration of intervention was 12 h ( $P < 0.05$ ) and then decreased gradually. The fact that the inward and outward currents of TRPM7 recorded on the CF cell membranes also took on corresponding trends in changes (first increasing and then decreasing) showed that the influence of Ang II on the cell is time-dependent to some extent. In the present study, the protein expression of collagen I also took on

the same change trend (first increasing and then decreasing), but it reached a maximum when the duration of intervention was 24 h, and then the expression decreased and took on the same change trend as was observed for the other two proteins.

In conclusion, the present study demonstrated that under the effect of Ang II at the concentration that had the maximum inducement effect on fibrosis, the protein expression level of TRPM7 by the CFs increased, the internal flow of  $Ca^{2+}$  increased and collagens I and III were expressed, promoting fibrosis. When the exposure to Ang II was prolonged, the induction of CFs to undergo apoptosis and necrosis increased, which may have given rise to various inflammatory reactions and further promoted fibrosis. The limitation of this study lies in that the experiment was conducted *in vitro*; therefore, it is necessary to conduct *in vivo* experiments with CFs to further verify the hypothesis that Ang II leads to cardiac fibrosis by mediating TRPM7 on the CF cell membrane.
