Abstract. The aim of this study was to investigate the safety and efficacy of selective laser trabeculoplasty (SLT) treatment of patients with primary open-angle glaucoma (POAG) who could not obtain target intraocular pressure (IOP) through post-trabeculectomy medication. Sixteen patients with POAG (18 eyes), who could not obtain target IOP following medication and surgery, were treated with 360° SLT. The IOP, anterior chamber inflammation, and daytime and long-term IOP fluctuations before and after SLT were documented. SLT treatment success was defined as >20% IOP reduction compared with the baseline IOP at 6 and 9 months after the laser treatment date. Prior to SLT, the patients were administered different types (average, 2.8±0.8) of anti-glaucoma drugs and had an average IOP of 21.3±3.4 mmHg. Following SLT, the average IOP decreased to 16.2±3.0 mmHg and the success rate was 77.7%. The pre-SLT daytime IOP fluctuation was 4.1±1.4 mmHg, which decreased to 2.6±1.1 mmHg following the laser treatment (P<0.05). In conclusion, this study demonstrated that SLT could reduce the IOP in post-trabeculectomy patients with POAG, and reduce the daytime IOP fluctuations.

Introduction

In 1983, Anderson and Parrish (1) found that specific optical radiation could damage pigmented structure. Theoretically, this effect could be applied to target tissues. In 1995, Latina and Park (2) applied this concept and were the first to conduct laser-selective treatment of the pigment-containing trabecular meshwork. They showed that a specific wavelength laser could selectively hit the pigment-containing trabecular cells. Selective laser trabeculoplasty (SLT) uses the Q-switch doubling frequency 532 nm neodymium-doped yttrium aluminium garnet (Nd:YAG) laser with a pulse time of 3 nsec and a diameter of 400 µm to irradiate the trabecular meshwork. SLT selectively targets the pigmental trabecular cells, while the non-pigmental trabecular cells and the surrounding tissues are not affected by the laser energy. The high selectivity and extremely short laser pulse time can reduce the damage to the surrounding non-pigmented trabecular tissues. In a previous study, no coagulation due to thermal damage was observed in the tissues following SLT; however, pigment granules were disintegrated within trabecular cells and there was destruction of pigmental trabecular cells (3). By contrast, the surrounding cells and tissues that did not contain the pigments showed no changes. Therefore, SLT treatment is safe. In 2001, the Food and Drug Administration approved the clinical use of SLT and this provided a novel therapeutic approach for primary open-angle glaucoma (POAG) (4).

SLT has been widely used in clinical treatment since 2002. Studies have shown that SLT can be used as one of the initial treatments of patients with POAG or in combination therapy when the maximum-tolerated medical therapy does not obtain satisfactory therapeutic effects (5-8). SLT can also be used as a therapeutic method to reduce the effective dose of anti-glaucoma drugs (9,10). However, there have not been any reports on the use of SLT as a treatment of post-trabeculectomy patients with POAG.

Trabeculectomy is still considered the mainstay for medically uncontrolled glaucoma (11). Studies have shown that, even when anti-metabolic drugs are applied during surgery, the five-year success rate of trabeculectomy is 60-80% (12) and the 15-year success rate is 52-59% (13,14). The postoperative filtering bleb scarring is the most important reason for surgical failure (15). The application of antimetabolites (such as mitomycin C) can reduce the scarring caused by filtering blebs and improve the surgical success rate, but certain patients remain who, due to a number of reasons, fail the surgeries. Trabeculectomy failure normally needs further laser or surgical intervention if the maximum medical therapy is insufficient. The difficulty of repeat trabeculectomy in these
Materials and methods

Patients. Patients who were diagnosed with POAG and who underwent one or more trabeculectomies between May and December 2012 in the Zhongshan Ophthalmic Center, Sun Yat-sen University (Guangzhou, China) were selected for this study. Following the surgery, 16 patients (18 eyes) could not obtain the target IOP following the application of one or several anti-glaucoma drugs. This included 14 males (15 eyes) and two females (three eyes). The follow-up period was 6-9 months (Table I). This study was conducted in accordance with the Declaration of Helsinki and with approval from the Ethics Committee of Sun Yat-sen University. Written informed consent was obtained from all participants.

Inclusion criteria. Patients had to meet the diagnostic criteria of POAG established by the International Society of Geographical and Epidemiological Ophthalmology (17). As such, the patient had to i) have lost the majority of his/her vision with only a 5-10˚ central or temporal vision island and have an eyeground exhibiting the typical depression of glaucomatous optic papilla and a cup/disc (C/D) area ratio of ≥0.8, with a mean deviation of <12 dB; ii) have undergone one or more trabeculectomy surgeries, and been prescribed one or more anti-glaucoma drugs without obtaining the target IOP; iii) have a previous history without other ocular surgery; iv) have a previous history without diabetes and hypertension; v) not plan to become pregnant during the treatment and observation period; vi) be able to be followed-up on schedule; and vii) continue their medication for at least three months before SLT.

Exclusion criteria. The exclusion criteria were as follows: i) Other types of open-angle glaucoma; ii) achievement of the target IOP following the trabeculectomy; iii) the patient had previously undergone argon laser trabeculoplasty or other eye surgeries; iv) the other eye of the patient was blind; v) systemic or ocular disease requiring corticosteroid therapy; and vi) the patient was <18 years old.

Treatment termination indicator. If the intra-experimental IOP reached 30 mmHg for >4 h, the IOPs of two post-treatment consecutive re-checks were higher than those prior to the treatment or serious complications occurred, the experiment was terminated.

Criteria for successful treatment. The treatment was considered to be successful if i) the IOP following the laser treatment was reduced by >20% compared with the baseline IOP prior to the treatment, and ii) there were no serious complications.

Observation parameters and evaluation indicators. The best corrected visual acuity (BCVA) was determined with the international standard vision chart. Slit-lamp examination was performed by observing the cornea, anterior chamber depth, lens and vitreous body. The Goldman IOP was checked each time. The ultrasonic corneal pachymeter (DGH 1000; DGH Technology, Inc., Exton, PA, USA) was used to measure the central corneal thickness three times, and the average was calculated. IOP determination was performed using the Goldman applanation tonometer (AT 900 R®, Haag-Streit USA, Inc., Mason, OH, USA); the IOP was measured three times and the average IOP was calculated. The Goldman applanation tonometer (AT 900 R®, Haag-Streit USA, Inc. Mason, OH, USA) detection time-points were 8:00 a.m., 10:00 a.m., 12:00 a.m., 2:00 p.m. and 5:00 p.m. These detection time-points are referred to as IOP fluctuation during day time. The detection time-point for each measurement of IOP after the follow-up visit was 10:00±1 h in the morning. Each measurement refers to the measurement of IOP for the follow-up after 1, 3, 7 days and after 1 month. Daytime IOP curve tracing was performed by checking the daytime IOP curves prior to the treatment and those three, six and nine months after the treatment. The daytime IOP fluctuation was equal to the highest daytime IOP measured minus the minimum daytime IOP measured. The main postoperative complications were observed, the eyeground was examined by direct ophthalmoscopy and the C/D ratio was recorded.

SLT treatment. The 360° SLT treatment was performed by the same physician for all patients in this study. The Ellex SOLO® SLT Nd:YAG laser treatment apparatus (Ellex Medical Pty Ltd., Adelaide, Australia) was used. The doubling frequency Q-switch Nd:YAG laser had a single pulse of visible light, a wavelength of 532 nm, a pulse width of 3 nsec, a facula spot diameter of 400 μm and an energy range of 0.3-2.6 mJ. The initial energy of the laser was set to 0.8 mJ, with 0.1 mJ as the amplitude value when increasing or decreasing the laser energy. When the bubbles formed, the laser energy was reduced by 0.1 mJ for the treatment. The single and non-repeated laser spot treatment was performed towards the trabecular meshwork along the nasal or temporal side. The treatments in each quadrant were performed ~25 times, with a 360˚ chamber angle.

Statistical analysis. The SPSS 18.0 statistical package (SPSS, Inc., Chicago, IL, USA) was used to analyze the data for significance. The continuous variables with normal distribution were assessed using the bilateral Student’s t-test or t-matching test, while the variables that did not meet the normal distribution were analyzed using the Mann-Whitney U test.

Results

The preoperative age, IOP, BCVA, refraction, corneal thickness and C/D ratio are shown in Table I. The average
number of trabecular surgeries received by all the patients was 1.7±0.5 (range, 1‑3). The post‑glaucoma surgery time was 2.4±1.1 years and the average follow‑up time was 6.3 months.

Preoperative medication. The average number of preoperative medications prescribed per patient was 2.8±0.8. A total of 22.2% of the patients used four anti‑glaucoma eye drop medications, 38.9% of the patients used three anti‑glaucoma eye drop medications and 38.9% of the patients used two anti‑glaucoma eye drop medications.

IOP. The preoperative IOP in this patient population ranged between 17 and 32 mmHg, with the average at 21.3±3.4 mmHg. The postoperative 2‑h IOP ranged between 12 and 27 mmHg, with the average at 17.8±4.0 mmHg. The postoperative one‑day IOP was 8‑24 mmHg, with the average at 14.2±3.9 mmHg. The postoperative seven‑day IOP was 12‑22 mmHg, with the average at 16.5±2.8 mmHg. The postoperative one‑month IOP was 11‑20 mmHg, with the average at 15.5±2.5 mmHg. The postoperative three‑month IOP ranged between 10 and 24 mmHg, with the average at 15.9±3.1 mmHg. The postoperative six‑month IOP ranged between 11 and 26 mmHg, with the average at 16.9±3.9 mmHg. The postoperative nine‑month IOP ranged between 11 and 19 mmHg, with the average at 16.2±3.0 mmHg. The IOP time curve is shown in Fig. 1. The postoperative IOP decreased significantly when compared with the preoperative IOP (t=5.820, P<0.001). The IOP of all the patients prior to SLT was >15 mmHg and the IOP of 77.8% of the patients was >18 mmHg, with the average follow‑up period of 6.3 months. The IOP of 27.8% of the patients was <15 mmHg, and the patients with an IOP>18 mmHg saw a reduction in their IOP by 16.7%. The changes in IOP distribution prior and subsequent to SLT are shown in Fig. 2. Three patients failed the treatment, one patient was prescribed anti‑glaucoma medication, and two patients received the second anti‑glaucoma surgery.

Success rate. The reduction in IOP in all the patients (100%) was ≥20% one day after the treatment. In the last follow‑up, 77.7% of the patients had a reduction in their IOP of ≥20%.

Effect of SLT on IOP fluctuation. The average IOP fluctuation prior to SLT was 4.1±1.4 mmHg, and the postoperative IOP fluctuation was 2.6±1.1 mmHg (t=3.424, P=0.003).

Adverse reactions. The most common postoperative adverse reactions were mild anterior chamber inflammation, mild eye pain, fuzzy vision and pink eye, which returned to normal 24‑48 h after the procedure. None of the patients appeared to have transient ocular hypertension. The gonioscopy was performed in the late follow‑up and revealed no formation of peripheral anterior synechia (Table II).

Discussion

Clinically, glaucoma treatment has focused on reducing IOP. It has been recognized that reducing IOP to normal levels is insufficient in the control of IOP in patients with advanced glaucoma (18). The different disease course of glaucoma and the different degrees of optic nerve damage can result in a different tolerance of retinal ganglion cells and lamina cribrosa towards IOP. Therefore, the target IOP specific to each patient with glaucoma must be determined. The concept of a target IOP is not only dependent upon the ‘individual tolerance pressure’, but is also determined by the threshold pressure. The threshold pressure is the IOP under which there would be no further damage to the glaucomatous optic nerve during treatment or follow-up. Under this IOP, the loss rate of retinal ganglion cells would not be greater than that induced by age, and the optic neuropathy may be decelerated or even terminated. Practice has proven that IOP reduction can effectively control the damage to the visual field in glaucomatous patients, and can delay the progression speed of glaucomatous optic neuropathy. Furthermore, fewer fluctuations in IOP can reduce the glaucomatous visual impairment. Patients with advanced glaucoma require reduced IOP to protect the already-damaged optic nerves (19,20).

The tolerance of optic nerves in patients with advanced glaucoma towards IOP is significantly decreased and, in order to prevent further glaucomatous damage, it is best to reduce the IOP to <15 mmHg (21,22). All the patients in this study were patients with advanced POAG, and the average post-glaucoma surgery time was 2.4 years. The patients had received anti-glaucoma surgery 1.7 times, on average, and the average number of anti-glaucoma medications received by each patient was 2.8. The average preoperative IOP was 21.3 mmHg. During the final post-SLT follow-up, the mean postoperative IOP decreased to 16.2 mmHg, with the success rate at 77.7%. In this study, the IOP of all the patients was >15 mmHg prior to SLT, and the IOP of 77.8% of the patients was >18 mmHg. Following SLT, the IOP of 27.8% of the patients was <15 mmHg, and 83.3% of the patients had an IOP of ≤18 mmHg. The average reduction amplitude of SLT in the patients with advanced POAG that had received the filtering surgery was ~5.1 mmHg, which was the same as the therapeutic results of those who had not received the filtering surgery (4). A previous study showed that each 1 mmHg reduction in IOP in patients with advanced glaucoma reduced their vision loss by 10% (18,23). Studies of advanced glaucoma therapy have also shown that the level of IOP is positively correlated with the visual field damage (24,25). During the six-year follow-up, the patients with an average IOP of <18 mmHg had little or no vision loss, while those with an IOP >18 mmHg exhibited clear and progressive vision damage. The SLT decreased the IOP of 83.3% of the patients to <18 mmHg (22,23). Therefore, in patients with advanced glaucoma, SLT can further reduce the IOP of the patient based on the application of anti-glaucoma drugs, helping the patient achieve or approach the target IOP. This would be an important factor in the protection of the optic nerve in patients with advanced glaucoma.

During the IOP reduction in the patients with advanced POAG, it is also necessary to further reduce the IOP fluctuations. The normal IOP fluctuation range is 3-6 mmHg, while the IOP fluctuation of patients with POAG would be significantly higher, 2-3-fold that of the IOP fluctuation in the normal population. In patients with POAG, the IOP fluctuation should be strictly controlled, and a number of studies have emphasized the importance of regulating these fluctuations (24,25). In the present study, SLT could not only further reduce the IOP of the patients, which could not be achieved through post trabeculectomy medication, but it could also reduce the post trabeculectomy IOP fluctuation in patients with advanced glaucoma. Köthy et al (26) reported that SLT could reduce the daytime IOP fluctuation of patients with POAG. Nouri-Mahdavi et al (27) performed the Advanced Glaucoma Intervention Study (AGIS) and found through regression analysis that the IOP fluctuation (daytime or intra ‑follow ‑up) could predict the glaucomatous visual field progression. IOP fluctuations were more important than the average IOP, and only when the IOP fluctuation was excluded was the average IOP value meaningful. Every additional 1 mmHg in IOP fluctuation [standard deviation (SD)] resulted in a 30% increased risk of visual field progression. The five-year observation results of the AGIS showed that the long-term IOP fluctuation of ≤±3 mmHg (SD) caused significant visual field progression, while the IOP fluctuation of <3 mmHg helped to reduce the visual field progression. The patients with a long-term IOP fluctuation of <3.1 mmHg were found to have a 2.89-fold greater risk of visual field progression than patients with a 2 mmHg fluctuation (28). The study by Hong et al (29) in 2007 revealed that an IOP fluctuation of >2 mmHg would also increase the risk of visual field damage progression, even if the IOP was <18 mmHg. An IOP fluctuation of <2 mmHg would be better able to prevent the vision damage. Thus, in the treatment of advanced glaucoma, one would not only need to control the IOP at levels below the target IOP, but also reduce the glaucomatous visual field damage caused by the IOP fluctuation.

In the present study, when patients received the post-trabeculectomy SLT, the average IOP fluctuation was reduced from the preoperative value of 4.1 mmHg to the postoperative value of 2.6 mmHg, and this difference was significant (P<0.05). The results revealed that SLT could not only reduce the post ‑ trabeculectomy mean IOP in patients with advanced glaucoma, but could also control the daytime IOP fluctuation. In glaucomatous patients with advanced visual field changes, the reduction in IOP fluctuation would exhibit positive effects towards the protection of the visual function of the patient.

With regard to the three patients who failed the treatment, two received additional anti-glaucoma drugs and one underwent filtering surgery treatment. All the patients exhibited an IOP reduction, with the greatest reduction observed one day after the surgery. None of the patients exhibited serious complications, such as transient high IOP, peripheral anterior synchiae or uveitis.

The chamber angular structure of the patients with POAG was not changed following the trabeculectomy, which provided the conditions for the SLT treatment. In terms of the validity of SLT as a method to further reduce IOP following trabeculectomy, our study showed that SLT safely, effectively and easily reduced the IOP, with few side-effects, and provided a viable alternative for treating patients with advanced POAG.
The follow-up of these patients should be further extended, and a control study should also be conducted to observe the effects of SLT on IOP fluctuations.
