Abstract. The abnormal activation of glycogen synthase kinase 3β (GSK3β) is one of the mechanisms involved in the pathogenesis of Alzheimer's disease (AD), which results in amyloid β-peptide (Aβ) plaque overproduction, Tau hyperphosphorylation and neuronal loss. A number of studies have reported that the activation of the mammalian target of rapamycin (mTOR) contributes to the generation and deposition of Aβ, as well as to the formation of neurofibrillary tangles (NFTs) by inhibiting autophagy. GSK3β is also involved in the mTOR signalling pathway. However, whether the inhibition of the activation of mTOR via the regulation of the function of GSK3β affects the pathology of AD remains unclear. In this study, we intraperitoneally injected amyloid precursor protein (APP)/presenilin-1 (PS1) transgenic mice with rapamycin, a known activator of autophagy that inhibits mTOR. Our results revealed that rapamycin treatment decreased senile plaque deposition by reducing APP generation, and downregulating β- and γ-secretase activity. Rapamycin also increased Aβ clearance by promoting autophagy and reduced Tau hyperphosphorylation by upregulating the levels of insulin-degrading enzyme. Additionally, rapamycin markedly promoted the proliferation of differentiated SH-SY5Y cells stably transfected with the APPswe gene and prevented neuronal loss in the brains of mice in a model of AD. Moreover, rapamycin induced autophagy and promoted autolysosome degradation. In this study, we provide evidence that rapamycin inhibits GSK3β activation and elevates β-catenin expression by improving the Wnt3a expression levels, which facilitates the amelioration of AD pathology. On the whole, our findings indicate that rapamycin inhibits the activation of mTOR and alters the Wnt/GSK3β/β-catenin signalling pathway; thus, it may serve as a therapeutic target in the treatment of AD.

Introduction

Alzheimer's disease (AD) is a progressive, irreversible neurodegenerative disease and is characterized by neuronal loss, neurofibrillary tangles (NFTs) of hyperphosphorylated Tau and amyloid β-peptide (Aβ) protein accumulation (1,2). Progressive synapse loss and cell death, particularly in the frontal cortex and the hippocampus region, is characteristic of AD and eventually leads to severe memory loss. The progressive accumulation of Aβ peptides and Tau hyperphosphorylation can enhance the assembly of NFTs and the formation of senile plaques (SPs); the latter exert additional toxic effects on neuronal function and cognitive function (3,4).

In recent years, a number of studies have found that glycogen synthase kinase3β (GSK3β) is a key modulator of the pathogenesis of AD. It has been demonstrated that GSK 3β contributes to Aβ-induced neuronal toxicity, and Aβ production and accumulation is promoted by GSK3β activators and is reduced by GSK3β inhibitors (5-8). Additionally, the overexpression of GSK3β increases Tau hyperphosphorylation (9,10), and the inhibition of GSK3β activity reduces Tau hyperphosphorylation, restores spatial memory deficits, and decreases neuronal cell death (11). GSK3β is also a pivotal regulator of the Wnt/β-catenin signalling pathway, which is closely related to the pathogenesis of AD (12,13).

Increasing evidence has indicated that the activation of mammalian target of rapamycin (mTOR) signalling contributes to the progression of AD and eventually exacerbates AD pathology and clinical manifestation (14,15). Therefore, mTOR inhibitors may be effective drugs for the treatment of AD (16). GSK3β is also involved in the mTOR signalling pathway. However, it remains unclear as to whether the inhibition of the activation of mTOR via the regulation of the function of GSK3β can prevent the progression of AD. In this study, we found that GSK3β activity was inhibited following treatment with rapamycin, which decreased Aβ deposition and increased Tau clearance. The data of this study suggest that rapamycin can attenuate the development of AD by activating the Wnt pathway and inhibiting GSK3β, in addition to inducing autophagy, thus providing a novel target for AD therapy.

Materials and methods

Mice and drug treatment. A total of 20 4-month-old amyloid precursor protein (*APP*)/presenilin-1 (*PS1*) double-transgenic mice overexpressing *mouse/human APP* (*Mo/Hu Aβ PP695swe*) and mutant *human PS1-Δ9*, weighing 22-25 g, were purchased from Beijing HFK Bioscience Co. Ltd. Mice were housed in individually ventilated cage (IVC) systems in a 12-h light/dark cycle, with free access to water and food. All procedures involving animals were performed under institutional guidelines. This study was approved by The Ethics Committee of Chongqing Medical University (SCXK 2014-0004). Ten male mice were randomly divided into the rapamycin group and the control group, 5 mice per group. The mice in the rapamycin group were treated with rapamycin at 2 mg/kg per day for 4 weeks, while the mice in the control group were administered the same volume of the solvent as the rapamycin group. Rapamycin (Gene Operation, Ann Arbor, MI, USA) was first dissolved in dimethyl sulfoxide (DMSO) and then diluted with double deionized water containing 5% Tween-80 and 5% PEG 400 immediately prior to intragastric administration. The body weight of the mice was recorded.

Routine blood analysis and chemical detection. Drug safety was evaluated by a routine blood examination and chemical detection. Blood was obtained from the lateral caudal vein of the mice (approximately 200 μl per time). The supernatants of the blood samples obtained by centrifugation (1,500 x g for 15 min) were kept at room temperature for 1 h and were then collected for chemical testing, including the quantification of alanine aminotransferase (ALT), aspartate aminotransferase (AST), blood urea nitrogen (BUN), triglyceride (TG), serum creatinine (Scr) and total bilirubin (TBIL). Routine blood tests consisted of a red blood cell (RBC) count, mean corpuscular volume (MCV), white blood cell (WBC) count, haemoglobin (HGB), mean platelet volume (MPV) and a platelet (PLT) count.

Brain tissue preparation. Mice were intraperitoneally injected with 10% chloral hydrate (400 mg/kg) and sacrificed by carbon dioxide (CO_2) euthanasia (CO_2 percentage volume displacement is 20%/min). For each mouse, half of the brain was used for protein extraction, and the other half was post-fixed in cold 4% paraformaldehyde (PFA) in 0.1 M phosphate-buffered saline (PBS) for 24 h. Following dehydration and embedding with optimal cutting temperature (OCT) compound (Sakura Finetek USA, Inc., Torrance, CA, USA), the fixed brain tissues were cut into 10-μm-thick coronal sections using a microtome (Leica Microsystems, Wetzlar Germany).

4G8 staining and thioflavin S staining. The slides were developed with methanoic acid for 10 min at room temperature before being blocked in 0.1% Triton and 5% BSA. The sections were then incubated at 4°C with mouse anti-Aβ, 17-24 (4G8) antibody (800704; 1:250; BioLegend, San Diego, CA, USA) overnight. After washing, the slides were incubated at 37°C for 40 min with cy3-conjugated goat anti-mouse antibody (A0521; 1:200; Beyotime Biotechnology, Haimen, China). The mounted slides were observed using a TCS-TIV confocal laser scanning microscope (Leica Microsystems).

The slides were deparaffinised with clearing acetone for 15 min and hydrated by a series of graded ethanol (EtOH) solutions as follows: 100-80-70%. The sections were then washed with double distilled water followed by 0.1% potassium permanganate solution. The slides were subsequently incubated in filtered 1% aqueous thioflavin-S (1326-12-1; Sigma-Aldrich, Darmstadt, Germany) for 15 min at room temperature in the dark. The slides were then washed in a series of graded EtOH solutions of 80-70% and then washed 3 times with distilled water. The coverslip was mounted with aqueous mounting media, and the samples were observed under a TCS-TIV confocal laser scanning microscope (Leica Microsystems).

We counted senile plaques in half of the brains of the mice, including the whole cortex and hippocampus on each slice, and 3 mice in each group. All counts are made by the same individual who was blinded to the experimental conditions.

Cells, cell culture and treatment. Differentiated SH-SY5Y cells stably transfected with the APPsw gene (gift from the Laboratory of Translational Medical Research in Cognitive Development and Learning and Memory Disorders, Children's Hospital of Chongqing Medical University, Chongqing, China) were confirmed to be human through STR profiling. Cells were cultured in DMEM (Gibco/Thermo Fisher Scientific, Waltham, MA, USA) at 37°C with 5% CO_2 and 95% air (v/v) supplemented with 10% foetal bovine serum (FBS, Biological Industries, USA), 100 U/ml penicillin and 100 μg/ml streptomycin. Rapamycin (Gene Operation) was dissolved in DMSO and then diluted in the culture medium. The final concentration of DMSO was <0.1%. The control group was treated with the same concentration of DMSO. The cells were incubated in 96-well flat-bottom plates ($1.0x10^4$ cells/well) with 50 or 100 nM rapamycin for 24 h before cell proliferation was assessed.

Determination of cell proliferation. The cell proliferative ability was determined by a Cell-Light™ EdU Apollo® 488 In Vitro Imaging kit (RiboBio Co., Ltd., Guangzhou, China). Following treatment with 50 and 100 nM rapamycin, the cells were treated with 50 μM EdU for 2 h at 37°C. The cells were then fixed, permeabilized and exposed to 1X Apollo® reaction solution for 30 min. The cell nuclei were then counterstained with DAPI. After washing with phosphate-buffered saline (PBS), the samples were examined under a fluorescence microscope (Leica Microsystems). Each experimental condition was repeated in at 6 wells, and data were calculated from 3 independent experiments.

Detection of autophagy by mRFP-GFP-LC3 adenoviral vector. Differentiated SH-SY5Y cells stably transfected with the APPswe gene were plated in 24-well plates and transfected with mRFP-GFP-LC3 adenoviral vectors (Hanbio Biotechnology Co., Ltd. Shanghai, China) at 70-80% confluence. On the 2nd day following transfection, 50 or 100 nM rapamycin was added to the medium for 24 h. After fixing the cells with PFA, autophagy was observed under a TCS-TIV confocal laser scanning microscope (Leica Microsystems).

Western blot analysis. Tissues from the half brains of 3 mice from each group were lysed in RIPA lyses buffer

(Pierce/Thermo Fisher Scientific). The protein concentration was determined by BCA. Subsequently, 10 or 12% SDS-PAGE gels were used to separate proteins. The proteins were then transferred to polyvinylidene fluoride (PVDF) membranes (Immobilon-P, Millipore, Bedford, MA, USA). Subsequently, the membranes were blocked in 5% BSA (dissolved in double deionized water). The membranes were incubated with rabbit anti-LC3B antibody (L7543; 1:1,000; Sigma-Aldrich, St. Louis, MO, USA), rabbit anti-NeuN antibody (D4G40), rabbit anti-β-catenin antibody (D10A8), rabbit anti-p62 antibody (5114) (all 1:1,000; all from Cell Signaling Technology, Danvers, MA, USA), rabbit anti-Beclin 1 antibody (ab62557), mouse anti-Tau5 antibody (ab80579), rabbit anti-insulin degrading enzyme (IDE) antibody (ab133561), rabbit anti-PHF-1 antibody (ab184951), mouse anti-GSK3β antibody (ab93926), rabbit anti-BACE1 antibody (ab2077), rabbit anti-PS1 antibody (ab71181), mouse anti-APP mouse antibody (ab32136) (1:1,000; all purchased from Abcam, Cambridge, MA, USA), anti-phosphorylated GSK3β (1:1,000; sc81495; Santa Cruz Biotechnology, Santa Cruz, CA, USA), mouse biotin anti-Aβ, 17-24 antibody (1:250; 800704; BioLegend) and mouse anti-β-actin antibody (1:1,000; ABM0001-50; Zoonbio Biotechnology, Nanjing, China) at 4°C overnight. After washing, the membranes were incubated at 37°C for 40 min with horseradish peroxidase-conjugated secondary antibody (goat anti-mouse IgG, S0002 or goat anti-rabbit IgG, S0001, Affinity Biosciences, USA) at a 1:5,000 dilution. The membranes were washed again and treated with enhanced chemiluminescence (ECL) substrate (K12045; Advansta, Menlo Park, CA, Cincinnati, OH, USA). The membranes were then visualized with Gel Imaging Systems software and quantified by Quantity One image software (both from Bio-Rad, Hercules, CA, USA).

Statistical analysis. Data were analysed with GraphPad Prism 5.0 software. All results are expressed as the means ± standard error of the mean (SEM). Statistical comparisons between the control and rapamycin treatment groups were determined using a two-sample t-test or one-way ANOVA, followed by a Bonferroni test. The level of significance was P<0.05.

Results

Treatment with rapamycin decreases the deposition of senile plaques in APP/PS1 transgenic mice. To assess whether rapamycin treatment results in Aβ aggregation and deposition in the brain, coronal sections of rapamycin- and vehicle-treated mice were immunohistochemically and fluorescently stained for Aβ plaques using 4G8 antibody and thioflavin S staining, respectively. The results revealed that rapamycin treatment significantly reduced the number (6.333±0.471 vs. 11.390±0.964, t=4.712, P<0.001) and the area of SPs (12.610±0.622 vs. 30.670±1.193, t=13.420, P<0.001) in both the hippocampus and cortex of the mouse brains compared with the control treatment. Thioflavin S staining revealed that the rapamycin group had fewer fibrillary Aβ deposits than the control group (Fig. 1).

Rapamycin decreases Aβ generation. The expression levels of APP, BACE1 and PS1 in the mouse brains were measured by western blot analysis. Rapamycin treatment had no effect on the level of APP (100.000±8.173 vs. 96.220±12.590, t=0.252, P=0.806). However, the APP cleaving enzymes, BACE1 and PS1, were both decreased following treatment with rapamycin (100.000±3.900 vs. 81.150±2.637, t=4.005, P=0.016; and 100.000±0.520 vs. 86.320±0.766, t=14.790, P<0.001, respectively; Fig. 2).

Rapamycin accelerates the degradation of Aβ. The Aβ levels in the mouse brains were then examined. The results of western blot analysis revealed that the Aβ level was markedly decreased by rapamycin treatment (100.000±4.185 vs. 68.060±2.442, t=6.591, P=0.003) compared with the control group. To examine the possibility that the Aβ reduction induced by rapamycin treatment is associated with Aβ clearance, western blot analysis was used to measure the levels of the Aβ degradation enzyme, IDE, in the mouse brains. The results revealed that IDE expression increased in the rapamycin group compared with the control group (100.000±2.418 vs. 139.900±6.851, t=5.495, P<0.001; Fig. 3).

Rapamycin decreases the levels of total Tau and abnormal hyperphosphorylated Tau. The anti-Tau antibody, Tau 5, was used to measure the total Tau level. We found that the total Tau level in the rapamycin treatment group was significantly decreased by 10.488% compared with that in the control group (100.000±1.187 vs. 75.450±6.672, t=3.622, P=0.005). In AD-affected brains, the aberrant hyperphosphorylation of Tau induces the formation of paired helical filaments (PHFs), which contributes to the formation of NFTs (17). In the present study, the PHF-1 levels were decreased by 12.430% in the rapamycin group compared with the control group (100.000±3.776 vs. 87.570±2.320, t=2.805, P=0.049; Fig. 4).

Rapamycin increases cell proliferation. The effects of rapamycin on cell proliferation were assessed by an EdU incorporation assay. Quantitative analysis revealed that the number of EdU-incorporated cells was significantly increased by treatment with 50 nM (43.020±0.303 vs. 47.280±0.831, t=4.943, P<0.01; F=42.72; P<0.001) and 100 nM (43.020±0.303 vs. 50.980±0.578, t=9.236, P<0.001; F=42.72; P<0.001) rapamycin (Fig. 5A and B). The neuronal nuclei (NeuN) antigen is a neuronal nuclear marker. The results of western blot analysis revealed that rapamycin treatment elevated NeuN expression in the brain tissues compared with the control group (100.000±4.618 vs. 189.600±4.156, t=14.420, P<0.001) (Fig. 5C and D).

Rapamycin induces autophagic activities. The treatment of differentiated SH-SY5Y cells stably transfected with the APPswe gene with 50 and 100 nM rapamycin markedly increased the number of mRFP-positive cells (1.333±0.882 vs. 42.670±3.712, t=5.369, P<0.01; 1.333±0.882 vs. 36.000±8.622, t=4.503, P<0.05, respectively; F=16.62, P=0.004) and 100 nM rapamycin treatment also increased the number of GFP-positive puncta (1.000±0.577 vs. 20.330±5.783, t=4.028, P<0.05; F=8.270, P=0.019; Fig. 6A and B). Rapamycin treatment at 50 nM increased the number of autolysosomes (0.333±0.333 vs. 34.330±2.963, t=9.016, P<0.001; F=40.770, P<0.001), and 100 nM treatment increased the number of

ratio of LC3-II/I (100.000±0.672 vs. 145.900±12.850, t=3.565, P=0.024) and the level of Beclin-1 in the brains of mice with AD (100.00±7.571 vs. 188.4±16.590, t=4.844, P=0.008), both of which are markers of autophagy initiation. Subsequently, we measured the expression of the p62/SQSTM1 protein, which is a lysosomal degradation substrate and dysregulated autophagy increases its elimination (18). The p62 level in the rapamycin group was decreased compared with that of the control group (100.00±2.988 vs. 144.200±18.590, t=2.346, P=0.041; Fig. 6D and E).

Rapamycin activates the Wnt/GSK3β/β-Catenin signalling pathway. The Wnt and mTOR pathways have been confirmed to be linked to GSK 3β in heart disease (19). Therefore, in this study, we detected whether rapamycin, an mTOR inhibitor, alters the Wnt pathway in AD. The results of western blot analysis revealed that Wnt3a was activated by rapamycin treatment (100.000±3.202 vs. 124.000±4.119, t=4.593, P=0.010) and that its downstream target protein, GSK3β, was inhibited by rapamycin treatment (100.00±6.805 vs. 81.600±3.051, t=2.467, P=0.033). Phosphorylation at the serine 9 residues of GSK3β downregulated its kinase activity, and rapamycin treatment increased phospho-GSK3β (Ser9) levels (100.00±4.607 vs. 144.700±8.587, t=4.590, P=0.001), compared with GSK3β. β-catenin is a target protein of GSK3β, and the activation of GSK3β inhibits its activity. The β-catenin expression level in the rapamycin group was elevated compared to the control

group (100.000±0.211 vs. 155.000±15.680, t=3.509, P=0.006). All these data suggest that rapamycin activates the Wnt pathway via the suppression of GSK3β (Fig. 7).

Drug safety of rapamycin as reflected by routine blood analysis and biochemical detection. Following treatment with rapamycin for 4 weeks, we first measured the drug safety of rapamycin by routine blood analysis (Table I) and chemical detection (Table II). The results of the routine blood tests and chemical detections did not differ significantly between the control and rapamycin-treated groups (all P>0.05), which indicates that this dosage of rapamycin caused no toxic effects *in vivo* compared with the control group.

Discussion

The increased production and accumulation of Aβ are the primary pathological features of AD and are closely associated with neurotoxicity and the decline in cognitive function. APP/PS1 double transgenic AD model mice are an ideal animal model with which to investigate the pathogenesis and drug targets of AD. Mutations associated with the familial form of AD are present in the amyloid precursor gene APP and in the presenilin genes 1 and 2, which are involved in the cleavage of APP and thus in the generation of Aβ. Aβ generated within cells is the suspected source of fibrillar Aβ plaque deposits, and elevated intracellular Aβ in the absence of SP
Figure 5. Rapamycin increases cell proliferation. formation has been reported to be accompanied by cognitive deficits (20). Aβ is produced from APP processing, in which APP can be sequentially cleaved by β-secretase (BACE1) and γ-secretase (PS1) to produce amyloidogenic peptides. In addition, the dynamic balance of Aβ is maintained by its production and degradation. Several proteases can regulate the degradation of Aβ, such as neprilysin (NEP), zinc metallopeptidases, and the carefully studied IDE (21,22). IDE is a zinc-endopeptidase that is well known for its activity against insulin and glucagon (23). However, recent studies have confirmed that IDE is a major endogenous Aβ-degrading enzyme. Additionally, IDE has been found to increase the secretion induced by Aβ in the presence of autophagy from astrocytes (24). Rapamycin-activated autophagy in conjunction with increased IDE secretion from astrocytes and IDE located in autophagosomes was discovered in a previous study. These findings imply that the IDE secretion induced by Aβ is regulated by autophagy, which is in accordance with the conclusion of this study. In this study, the results of immunofluorescence revealed that rapamycin treatment reduced SP formation and deposition. The results of western blot analysis demonstrated that rapamycin decreased the expression levels of BACE1, PS1 and Aβ, and increase the

level of IDE, which illustrates that rapamycin can ameliorate Aβ accumulation, by not only enhancing autophagy activity, but also by reducing APP cleavage and increasing the proteolytic degradation of Aβ.

Tau is the most abundant microtubule-associated protein in the brain. Under physiological conditions, the function of Tau is to combine with microtubules to promote microtubule stabilization. However, by contrast, under pathological conditions, Tau exhibits altered solubility properties, is abnormally hyperphosphorylated at certain residues and forms PHF structures, which are prone to form NFTs (17,25,26). It has been confirmed that Tau can be eliminated by autophagy under pathological conditions (27,28). The inactivation of autophagy leads to the accumulation of hyperphosphorylated Tau, and the activation of autophagy results in a reduction in hyperphosphorylated Tau levels (29). Notably, it has been demonstrated that different lengths of Tau may be degraded through different autophagic pathways; the full-length Tau is preferentially degraded through macroautophagy, whereas truncated Tau (for one, TauRDΔK280) is cleared through chaperone-mediated autophagy (30). Although the APP/PS1/Tau tri-transgenic AD mouse model is an ideal model with which to study the pathology of Aβ and Tau, the tau-induced pathology in the

APP/PS1 double-transgenic AD mouse model was also found in our previous study and in other reports (31-33). This study examined the effects of rapamycin on Tau clearance. The results of western blot analysis indicated that rapamycin treatment decreased the expression levels of Tau-5 and PHF-1, suggesting that rapamycin contributed to the degradation of not only full-length Tau, but also phosphorylated Tau.

AD is characterized by neuronal cell death, which eventually leads to memory loss. Neurons are post-mitotic cells that are unable to degrade the toxic substances accumulated during the ageing processes with mitosis; thus autophagy is an important mechanism for clearing abnormally aggregated proteins in

neuronal cells (34). It is becoming evident that autophagy is a protective reaction in neurons and that dysfunctional autophagy aggravates neuronal death in AD (35-37). NeuN, a marker of neuronal differentiation, is a nuclear protein expressed in most post-mitotic neurons in the nervous system and plays an important role in nervous system development and function (38). This study found that rapamycin treatment elevated NeuN expression levels and the number of EdU-positive cells, which indicates that rapamycin can increase cell proliferation and may exert a neuroprotective effect in AD.

Autophagy is a catabolic mechanism responsible for the clearance of intracellular cytosolic components, including
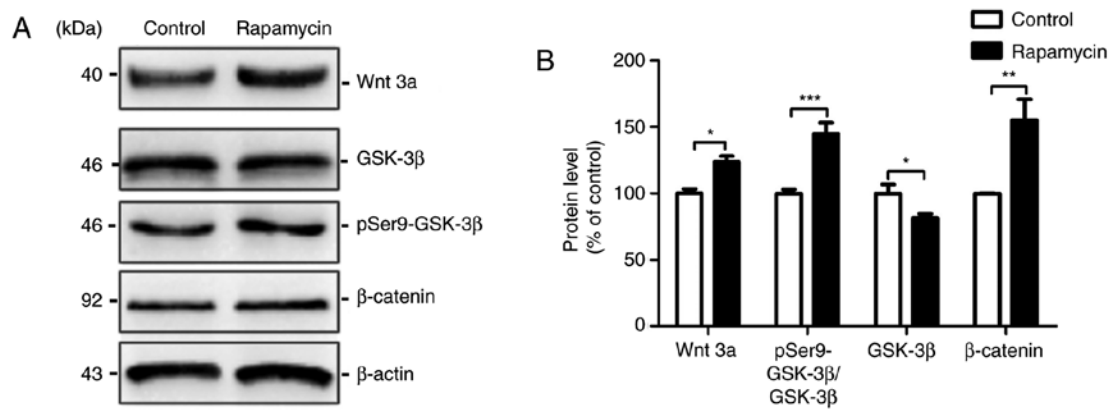

Figure 7. Alteration of the Wnt/GSK3β/β-Catenin signalling pathway via rapamycin administration were detected by western blot analysis. (A) The protein expression levels of Wnt3a, GSK3β, p-GSK3β and β-catenin were detected by western blot analysis (one representative image is shown, n=3). (B) Quantitative analyses of Wnt3a, GSK3β, p-GSK3β and β-catenin by immunoreactivity in the lysates of half brains from the control and rapamycin-treated groups. Data are presented as the means ± SEM and were analysed by a t-test (*P<0.05, **P<0.01 and ***P<0.001, compared with the control group). GSK3β, glycogen synthase kinase 3β.

Table I. Routine blood analysis following rapamycin treatment in mice (compared with the control group (P>0.05).

Indexes	Control group	Rapamycin group
RBC ($\times 10^{12}$/l)	10.7±0.6	10.5±0.3
HGB (g/l)	147.7±16.2	145.7±2.3
MCV (fl)	43.4±1.4	44.9±0.2
WBC ($\times 10^{9}$/l)	10.4±2.3	8.5±6.6
PLT ($\times 10^{9}$/l)	989.3±278.6	1,140.0±50.8
MPV (fl)	6.5±0.1	6.7±0.1

Table II. Biochemical detection of rapamycin administration effects on mice (compared with control group, P>0.05).

Indexes	Control group	Rapamycin group
ALT (U/l)	41.3±4.0	43.3±4.2
AST (U/l)	143.7±44.8	137.3±38.9
BUN (mmol/l)	11.2±0.6	10.8±2.0
Scr (μmol/l)	11.1±0.6	11.8±1.0
TBIL (μmol/l)	0.8±0.8	0.6±0.7
TG (mmol/l)	1.0±0.1	1.1±0.5

misfolded proteins, aggregates and organelles, and it has now been confirmed to play a crucial role in AD pathology. Properly functioning autophagy is essential for neuronal metabolism, and the lack of autophagy in the central nervous system (CNS) leads to neurodegeneration; for example, inactivating autophagy impairs neuronal homeostasis (29,39). Autophagy is initiated when an 'isolation membrane' appears. Subsequently, the membrane elongates, engulfing cellular components to form autophagosomes (APs) and lysosomes, which can digest the cargo in their acidic environment, fuse with APs to generate autolysosomes (ALs). Recent studies have found that the expression of autophagy-related genes is downregulated with ageing; a deficiency in Beclin1, a key protein in autophagy induction, results in increases in Aβ levels, whereas its overexpression reduces the accumulation of Aβ (40-43). These studies have indicated that autophagic activity is reduced with ageing, and the reduction of autophagy contributes to the onset of AD. Several studies which have focused on autophagy have discovered that the activation of autophagy can decrease abnormal Aβ aggregation in neurons and can alleviate neurotoxicity (44-48), which is consistent with the results of this study.

The transfection of cells with the mRFP-GFP-LC3 adenoviral vector allows for the visualization of autophagic activity. Upon rapamycin exposure, the cells accumulate dense red and yellow puncta, which represents autolysosomes and autophagosomes, respectively. The present study on rapamycin found that treatment with rapamycin increased the number of autolysosomes and autophagosomes. However, the results of western blot analysis indicated that rapamycin treatment increased the ratio of LC3-II/I and elevated the expression of Beclin1, both of which are crucial mediators of autophagy induction. p62 protein is a lysosomal degradation substrate that reduces when autophagy begins and the autophagic flux proceeds smoothly (18). In this study, the p62 expression level decreased following rapamycin treatment, which demonstrated the increased degradation mediated by autophagy.

GSK3β is one of the phosphorylating glycogen synthase enzymes (49). In the brain, GSK3β is involved in a number of cellular processes and mediates several signalling pathways (50-52). Researchers have reported that Aβ leads to GSK3β activation, and the inhibition of GSK3β has been verified to reduce Aβ production and decrease Aβ-induced neurotoxicity (53,54). It is well known that GSK 3β has the exact site for the hyperphosphorylation of Tau protein. The excessive activation of GSK 3β increases hyperphosphorylated Tau protein production, and GSK3β itself is involved in the initiation and development of AD (55). GSK 3β is most commonly mediated by inhibitory phosphorylation at the Ser9 site residue, and this serine can be phosphorylated by several kinases; thus, multiple signalling pathways

are involved in its regulation, such as the PI3k/Akt/mTOR pathway and the Wnt pathway. It has been reported that GSK3β functions in several pathways which regulate the cellular homeostasis of energy and growth, including those mediated by PI3K and AKT, mTOR and MAPK. The inhibition of mTOR by rapamycin leads to the inactivation of its target kinases, including AKT, p70S6K and p85S6K, which in turn promotes GSK3β activation (56-59). The Wnt pathway is also involved in the onset of AD. Wnt signalling is an autocrine signal transduction pathway that participates in brain development (60,61). The ablation of Wnt-3a, a Wnt ligand, results in the disappearance of the hippocampus (62,63). Wnt signalling can be mainly divided into two types: β-catenin-dependent signalling (Wnt/β-catenin) and β-catenin-independent signalling (64,65). GSK3β is a crucial regulator of the Wnt/β-catenin pathway. The activation of GSK3β by Wnt signalling results in the phosphorylation and degradation of its downstream target, β-catenin (66). Without Wnt stimulation, the phosphorylation of β-catenin prevents transcriptional activity in the nucleus.

In this study, 4 weeks of rapamycin administration significantly activated the Wnt pathway, which led to an increased Wnt3a and a reduced GSK 3β expression. The phosphorylation of GSK3β at Ser9 reduced the activation of GSK 3β, and treatment with rapamycin seemed to reduce the activity of GSK3β. It has been reported that the overexpression of GSK3β in neurons decreases nuclear β-catenin levels and increases Tau hyperphosphorylation in the hippocampus (10). In this study, the results of western blot analysis indicated that rapamycin treatment increased the expression level of β-catenin.

It has been reported that rapamycin improves learning after sepsis by enhancing autophagy and may be a potentially effective therapeutic agent for the treatment of sepsis-induced cognitive impairment (67,68). In this study, the data imply that rapamycin can increase cell proliferation as well as reduce Aβ and Tau pathology by inducing autophagy and activating the Wnt/GSK3β/β-catenin signalling pathway. Thus, rapamycin may be a potential therapy with which to prevent the progression of AD.

Rapamycin is a macrolide antibiotic produced by *Streptomyces hygroscopicus*, and a previous study found that rapamycin is an inhibitor of mTOR, which is a major signalling molecule that suppresses the initiation step of autophagy (69). Notably, GSK3β is a key regulator of many cellular signalling pathways, and the mTOR pathway is one of these pathways. However, the effect of rapamycin on the GSK3β signalling pathway has not yet been clearly elucidated. The purpose of the present study was to analyse the effects of rapamycin on AD progression, autophagy activity, and GSK3β function, as well as the underlying mechanisms of action of rapamycin in APP/PS1 double transgenic mice.

Availability of data and materials

All data generated or analyzed during this study are included in this published article.

Authors' contributions

GH and SL conceived and designed the study. JC and ZL performed the experiments and drafted the manuscript, YL and ML conducted the statistical analysis. All authors have read and approved the final manuscript.

Ethics approval and consent to participate

All procedures involving animals were performed under institutional guidelines. This study was approved by The Ethics Committee of Chongqing Medical University (SCXK 2014-0004).

Patient consent for publication

Not applicable.

Competing interests

The authors declare that they have no competing interests.
