Abstract. Fibroepithelioma of Pinkus (FEP), which is considered to be an uncommon variant of basal cell carcinoma, has been described in association with other systemic diseases. However, no specific studies are currently available on this subject. The aim of our study was to evaluate the clinical and morphological characteristics of FEP and investigate whether this rare tumor is a single entity or seen in the context of a more complex syndrome. We retrospectively analyzed 49 cases of FEP diagnosed and excised in a single academic institution from 1995 to 2011. The tumors were mainly located on the trunk (77.55%), followed by the lower extremities (12.20%) and the head and neck (10.20%). In 9 of the 49 cases (18%), FEP was associated with gastrointestinal tumors. The abovementioned cases are presented in an attempt to make clinicians more aware of a possible association between FEP and gastrointestinal cancer. Although a possible underlying common genetic background between FEP and gastrointestinal tumors was not provided, our study suggests that patients with FEP should be screened for the occurrence of gastrointestinal tumors.

Introduction

Fibroepithelioma of Pinkus (FEP) is considered to be an uncommon variant of basal cell carcinoma (BCC) (1), although it was recently described as a trichoblastoma (2,3). Clinically, FEP appears as a solitary non-pigmented or brownish to gray, well-outlined flat or polypoid lesion, with peculiar

dermoscopic and confocal aspects (4) and with a predilection for the lower trunk (Fig. 1).

Histopathologically, FEP is characterized by numerous thin anastomosing cords of basaloid cells extending downward from the epidermis into the dermis within a fibrotic stroma (Fig. 1).

Unlike the common types of BCC, FEP exhibits an overwhelming predilection for the trunk (particularly the lower back) and the extremities, with only 5% of the tumors arising on sun-damaged skin. The clinical differential diagnosis includes a wide spectrum of lesions, such as skin tags or dermal nevi. However, the diagnosis is easier when the clinical examination is combined with dermoscopy and confocal microscopy (4,5).

Although FEP was originally described by Pinkus as a variant of BCC, the nature of this tumor remains a subject of debate.

The strong predilection for the lumbar region (not sun-exposed area) and for the female gender differentiates FEP from other BCC subtypes that usually arise on sun-exposed areas and/or predominantly in men.

Furthermore, FEP exhibits a peculiar histopathological architecture, as well as the presence of Merkel cells, which are usually absent in BCCs but found in trichoblastomas.

Thus far, FEP has been described as a solitary lesion or in association with Paget's disease in a limited number of case series. However, no studies have been performed to investigate whether this lesion arises as an isolated rare tumor or in patients harboring specific diseases.

The aim of our study was the characterization of a consecutive series of FEPs to identify a possible association of this tumor with concomitant diseases.

Patients and methods

Cases. All the histopathologically-proven cases of FEP excised in a single referral center (Department of Dermatology, University of Modena and Reggio Emilia, Modena, Italy) from 1995 to 2011 were retrospectively reviewed. Clinical data including gender, location and age were recorded. Location was divided into head and neck, trunk, back, genitalia, upper extremities and lower extremities.

Figure 1. (A-J) Clinical and histological images of fibroepitheliomas of Pinkus (FEPs) collected in our Department. Clinically, FEP appears as a solitary non-pigmented, flat or polypoid lesion, most commonly localized on the trunk or the extremities: (A) Male, aged 50 years, with FEP of the trunk; (B) female, aged 36 years, with FEP of the trunk; (C) female, aged 32 years, with FEP of the left lower limb; (D) male, aged 63 years, with FEP of the left shoulder; (E) female, aged 38 years, with a FEP of the right lower limb; (F) male, aged 47 years, with a FEP of the trunk; (G) female, aged 39 years, with FEP of the left lower limb; (H) male, aged 59 years, with FEP of the trunk; (I) female, aged 44 years, with FEP of the trunk; and (J) female, aged 34 years, with FEP of the trunk. (A'-J') Histopathological images of the respective lesions: FEP exhibits numerous long, thin, branching and anastomosing cords of basaloid cells within a fibrotic stroma. Hematoxylin and eosin staining; original magnification, x5.

The data on excised tumors (skin tumors or visceral malignancies) were retrieved from the database of the Department of Pathology at the University of Modena and Reggio Emilia.

Moreover, the medical records of all the patients, such as radiological examinations or surgical procedures, were reviewed to obtain a complete picture of each patient's health status. The present study was conducted in accordance with the principles of the Declaration of Helsinki.

This study's protocol and the submitted manuscript have been approved by the Institutional Review Board of the Department of Surgery, School of Medicine, Dentistry and Morphological Sciences, University of Modena and Reggio Emilia (Modena, Italy).

Results

Association of FEP with cancer. A total of 49 cases of FEP were identified, mainly located on the trunk (77.55%), followed by the lower extremities (12.20%) and the head and neck (10.20%). The mean age of the patients was 64.04 years

and 31 of the patients were female (63%). The tumors found in patients with FEP are listed in Table I. Of the 49 patients, 9 (18%) were found to have gastrointestinal tumors, 4 patients (8%) had breast carcinoma and 7 patients (14%) had other cancers. More specifically, 6 patients had colonic adenocarcinoma and 3 patients had neuroendocrine gastrointestinal tumors. Of the 49 patients, 1 (3%) was affected with mammary Paget's disease and 1 with perianal extramammary Paget's disease.

In all but 2 cases, FEP appeared 1-2 years prior to the internal malignancies, whereas in these 2 cases the malignancies occurred synchronously with FEP.

Discussion

FEP is a rare tumor that is considered to be a variant of BCC, although its classification remains to be clarified. Moreover, the specific skin location and gender predilection differentiates this tumor from 'classical' BCC. Furthermore, BCC and FEP share certain characteristics, such as the expression of

Table I. Non-skin tumors diagnosed in patients with fibroepithelioma of Pinkus.

Tumors	Gender		Total n=49 (100%)
	Male, n=18 (37%)	Female, n=31 (63%)	
Gastrointestinal tumors	5 (28)	4 (13)	9 (18)
Upper	1 (20)	1 (25)	2 (22)
Lower	4 (80)	3 (75)	7 (78)
Colonic Adenocarcinoma	3 (60)	3 (75)	6 (67)
Neuroendocrine gastrointestinal tumor	2 (40)	1 (25)	3 (33)
Extramammary perianal Paget's disease	0 (0)	1 (3)	1 (2)
Mammary Paget's disease	0 (0)	1 (3)	1 (2)
Breast carcinoma	0 (0)	4 (13)	4 (8)
Other cancers	4 (22)	3 (10)	7 (14)

androgen receptor, which is minimal in trichoblastomas (6). However, FEPs and trichoblastomas display Merkel cells, which are usually absent in BCC (7).

In the present study, we observed an association between FEP and gastrointestinal tumors. FEP was previously reported in the literature in association with Paget's disease (7), breast cancer (8,9) and, as a variant of BCC, Gorlin-Goltz syndrome (10). However, conclusive epidemiological and biomolecular data on these clinical associations are currently lacking (11,12).

Considering our data, we may hypothesize a pathogenetic association between FEP and gastrointestinal neuroendocrine tumors, due to the common embryogenic origin of Merkel cells and neuroendocrine cells from the neural crest. Similar to the well-known genodermatosis (13), a common aberration of genes implicated in mesoectodermal differentiation may play a role in the pathogenesis of FEPs and gastrointestinal adenocarcinomas. Mutation in the tumor suppressor gene *TP53* may predispose to the development of FEP (14). Similar to BCC, it has been hypothesized that mutations in the Patched 1 gene (*PTCH1*), which is responsible for inhibitory signaling in the Hedgehog pathway, may also lead to the development of FEP.

In our study, we did not investigate for *PTCH1* mutations or another possible genetic background, although the association of FEP with gastrointestinal tumors appears to be part of a more complex, although still not well defined phenotype, rather than a coincidental finding.

Gastrointestinal tumors may be associated with either Gorlin-Goltz syndrome or trichilemmal lesions (13). As regards the latter condition, Cowden syndrome is characterized by the occurrence of several tumors, including breast, endometrial, thyroid, kidney and colorectal cancers, in association with dermatological manifestations such as oral/skin papillomas and trichilemmomas, and with *PTEN* mutations (13). Interestingly, dermatological signs may occur prior to systemic symptoms (13). If we consider FEP as a trichoblastoma, it appears more likely that this rare skin tumor should be considered to be part of the cutaneous spectrum of Cowden syndrome (in which hamartomas and colon carcinomas have been recently described) (15), or as a tumor associated with a new syndrome

including gastrointestinal tumors. Furthermore, our cases were characterized by early onset of FEP followed by the development of gastrointestinal tumors. This peculiar onset of dermatological diseases may be seen in the context of genodermatosis (12).

Although a possible underlying common genetic substrate between FEP and gastrointestinal tumors was not identified, our study included a consecutive large series of FEPs from a single academic institution, with a careful examination of the patients' medical history. However, additional cases are required to confirm this association and assess its predictive value. It is recommended that FEP patients are clinically evaluated and screened for gastrointestinal tumors. Our clinico-epidemiological findings raise the question of whether FEP is a single entity or part of a more complex and not yet defined gastrointestinal syndrome.
