Abstract. This study aims to investigate human papilloma virus (HPV) frequency in Brazilian patients with oral squamous cell carcinoma (OSCC) in order to establish a clinicopathological profile. It will also examine the correlation between patient survival and HPV expression in primary tumors (PTs), and their matched samples (MSs) of recidives, lymph nodal metastasis (LNM) or necropsies. Eighty-seven PTs and their corresponding 87 MSs were tested for HPV infection by polymerase chain reaction (PCR) using general and type-specific HPV primers. The following data were obtained from patient medical files: primary site, age, gender, tobacco consumption, histological differentiation, recurrences, metastasis, disease-free survival (DFS) and overall survival (OS). Of the 87 patients investigated, 17 (19.5%) were found to have HPV DNA in their tumors. An investigation of all the paraffin-embedded specimens revealed the presence of HPV DNA in 18 of the 174 samples (10.4%), 10 (11.5%) from PTs and 8 (9.2%) from MSs. No virus was detected in the corresponding PT of 7 (8.1%) MSs, and only one patient demonstrated HPV DNA positivity in both samples. The HPV genotypes 16 and 18 were detected in 4 (22.2%) and 3 (16.7%) of the positive samples, respectively. Infection with both genotypes was found in 6 (33.3%) investigated samples, and the HPV genotype was unidentified in 5 (27.8%) samples. The tongue was the most prevalent infected anatomical site. We did not find any significant association between HPV infection and gender, age, histological differentiation, DFS or OS. A significant number of HPV samples were positive among non-smoking patients. Although a possible influence of the virus on tumoral induction cannot be ruled out, the low frequency of OSCC cases that contain HPV does not suggest that this virus has the same etiological influence on patients as tobacco consumption does.

Introduction

Oral squamous cell carcinoma (OSCC) is the sixth most common malignancy worldwide. The overall survival (OS) has not changed in recent years, despite extensive research on its biological and molecular characteristics. The main problems in the clinical management of this malignancy are the high incidence of local-regional recurrence and the lack of early detection (1).

Tobacco and alcohol are well-established risk factors for OSCC, but it can also develop in individuals who have never smoked (2). Moreover, only a small proportion of tobacco-exposed individuals have developed OSCC, and there is an emerging tumoral population who lack exposure to the mentioned risk factors (3,4), suggesting that others factors can play a role in oral carcinogenesis.

Over the past 2 decades, the role of high-risk human papilloma virus (HPV) has been studied, and data supporting its role as a causative agent in the development and progression of a subset of OSCC has been controversial, with considerable variability in frequency depending on the population studied, tumor localization, quality of samples and technical resources utilized for HPV detection (5-7).

As is the case in cervical and anogenital carcinomas, the most frequently detected high-risk HPVs in OSCC were the 16 and 18 genotypes (4). High-risk HPV infection tends to be more persistent, and has been associated with tumoral recurrence episodes after surgical therapy in cervical carcinomas, which affects disease prognosis (8).

Evidence from several laboratories demonstrates that high-risk HPVs are involved in the etiology of OSCC. These data indicate that oral keratinocytes can be transformed with high-risk HPVs *in vitro* through mechanisms involving viral oncoproteins (9,10). Moreover, in some cases the HPV genotype identified in primary OSCC is maintained in nodal metastases (11,12).

In several later studies, HPV DNA was detected by methods such as polymerase chain reaction (PCR), Southern blotting and *in situ* hybridization in the sera and tumor tissue of OSCC patients (5,13), confirming previous data. Nowadays, PCR is considered the most sensitive method for the detection of HPV DNA in clinical specimens (14).

In a meta-analysis study including 4680 OSCC samples from 94 reports, the overall level of HPV prevalence in OSCC

Key words: oral cancer, HPV, oral squamous cell carcinoma, tobacco, prognosis

was 46.5%, in contrast to 10% in normal oral mucosa reported in 27 analyzed data sets. Moreover, high-risk HPVs were significantly more likely to be detected in OSCC specimens than low-risk HPVs (1).

The presence of HPV in OSCC has been investigated in different populations. Differences among the various populations were identified, with trends of higher frequencies in some population groups. In a study performed with a Mexican population, Ibieta *et al* found that 42% of their samples were HPV positive (15). In another investigation, conducted with Indian patients, Balaram *et al* found a high prevalence (75%) and multiplicity of HPV infections (3). Moreover, a 100% prevalence was found in a mixed Japanese/Chinese population (16). On the other hand, in a recent study with a Brazilian population, Rivero and Nunes found the complete absence of HPV DNA in the 17 fresh and 23 paraffin-embedded tissues that were evaluated (17).

The purpose of the present study was to investigate the presence of HPV in a Brazilian population sample of OSCC patients. Additionally, in cases with positive specimens, analysis was extended to clinicopathological profile characterization and to the correlation between patient survival and the presence of HPV DNA in primary OSCC tumors and in their corresponding matched samples (MSs) of recurrences, lymph nodal metastasis (LNM) and necropsies.

Materials and methods

Patients and samples. This study population is from two other previous studies, recently performed at our laboratories, focused on the prognostic factors associated with OSCC (18,19). Research was conducted on the medical files of patients with head and neck tumors, the histopathological diagnosis of OSCC was confirmed and paraffin-embedded specimens were selected.

The medical files were analyzed and reviewed in order to collect information concerning the age, gender, primary tumor site, tobacco exposure, metastasis, tumoral recurrences, histological grade classification, disease-free survival (DFS) and OS of the patients.

Following the collection of information from the medical files, the inclusion criteria for this study were applied, including: a) adequate clinicopathological data; b) availability of sufficient paraffin-embedded tumor material; c) presence of oral cavity cancer (including oral tongue, floor of mouth, gingiva, lips, buccal mucosa, hard palate and retromolar trigone) (20); d) no previous head and neck cancer; e) no prior oncological therapy; f) histologically-proven squamous cell carcinoma; g) a single lesion; h) absence of initial or distant metastasis. Patients with *in situ* and/or T4 tumors were excluded from this study.

Patients were classified as never, current or former daily (those who had quit for more than 12 months before diagnosis) tobacco smokers, and whether they smoked cigarettes, a pipe and/or cigars was taken into consideration (5).

Tumoral recurrence was defined as the occurrence of another carcinoma <2 cm away from the primary carcinoma (21). Tumors were classified as well- moderately- or poorly-differentiated according to the World Health Organization classification of histological differentiation grade (22). The

DFS was defined as the interval between the beginning of the treatment and the date of the first recurrence (local recurrence or metastasis) or last follow-up. The OS was defined as the interval between the beginning of treatment and the date of death or the last follow-up.

For the evaluation of possible HPV DNA tumoral persistence, two samples from each patient were investigated: primary tumor (PT) was selected as the initial sample and tumoral recurrence, LNM and necropsy occurrences were used as the corresponding MSs. For the MSs, the selected tumoral recurrence was taken from the same anatomical region (<2 cm away), the LNM from the most representative tumoral area and the necropsy specimens from irresectable tumors. The paraffin-embedded specimens with the highest tumoral area were selected for DNA analysis.

After surgical resection, the tumor tissues were routinely fixed in 4% neutral-buffered formalin, embedded in paraffin blocks and archived according to institution protocol. Later, the selected paraffin-embedded specimens were retrieved and processed to 5- μ m thick sections, stained with hematoxylin-eosin and reviewed by two medical pathologists (A.R.S. and S.Z.) to confirm the diagnosis and the histological classification grade.

One hundred and seventy-four paraffin-embedded specimens, 87 PTs and 87 MSs, that corresponded to the biopsy or surgical resection of 87 patients with histologically-confirmed primary OSSC were selected from the files of the Department of Pathology of the Ribeirao Preto School of Medicine General Hospital, University of Sao Paulo, Brazil, from 1990 to 2002. These specimens were sliced into 5- μ m thick sections and processed for DNA extraction. To prevent cross-contamination, the microtome blade was discarded after each block was sectioned, and the sections from the selected specimens were transferred to sterile 1.5-ml tubes with tweezers.

The study protocol was integrally approved by the local Ethics Committee according to HC-FMRP 7327/ 2004 process.

DNA isolation and internal control amplification. DNA was isolated from formalin-fixed paraffin-embedded tissue specimens with a Promega Tissue Kit according to the manufacturer's instructions (MagneSil® Genomic, Fixed Tissue System, Promega Corp., Madison, WI, USA). The DNA solutions were stored at -20°C.

DNA integrity and the absence of PCR inhibitors were verified by the amplification of a 110-bp fragment of the ubiquitous human β -globin gene (23). The primers were PC03 (5'-ACACAACCTGTGTTCACTAGC-3') and PC04 (5'-CAACTTCATCCACGTTCCACC-3') (Bioneer Inc., Daejeon, Korea) (24). Only samples with a visible β -globin band were included in this study. When a sample was negative for β -globin, an additional section was taken from the block and re-analyzed. Successful amplification of the β -globin gene fragment indicated that the DNA sample was adequate for HPV DNA analysis.

HPV DNA detection. We utilized the GP5+/GP6+ (Bioneer Inc.) consensus general primer pair to amplify a 150-bp fragment from the L1 gene of general HPV types (GP5+, 5'-TTTGTCTGTGTTAGTACTACTAC-3'; GP6+, 5'-GAAAAATAAACTGTAAATCATATTC-3') (25).

^aOthers anatomical sites include the retromolar trigone, buccal mucosa, gingiva and upper lip.

PCR was then performed on the HPV-positive DNA samples, to determine if they contained genotypes 16 and 18, using specific primers targeting ~100 bp in the E7 ORF: HPV-16E7.667 (5'-GATGAAATAGATGGTCCAGC-3'), HPV-16E7.774 (5'-GCTTTGTACGCACAACCGAAGC-3'), HPV-18E7.696 (5'-AAGAAAACGATGAAATAGATGGA-3') and HPV-18E7.799 (5'-GGCTTCACACTTACAACACA-3') (Bioneer Inc.) (26).

Polymerase chain reaction. Amplifications of general HPV genotypes and β -globin DNA were done in the same reaction. A PCR test was performed on each microtube, which contained 5 μ l of extracted genomic DNA and the addition of a mixture reaction containing 12.5 μ l PCR Master Mix® (Promega Corp.), 1.2 μ l PC03/PC04 primer, 4.3 μ l GP5+/GP6+ primer and 2.0 μ l sterile water, for a total volume of 25 μ l, and one mineral oil drop added to the surface of the mixture. The primers were added to a final concentration of 50 μ M. In the detection of specific HPV subtypes, the PCR mixture contained 5 μ l DNA sample, 12.5 μ l PCR Master Mix (Promega Corp.), 2 μ l HPV-16E7 or HPV-18E7 primers and 5.5 μ l sterile water.

For HPV general and specific genotype detection, PCR was performed with forty amplification cycles in a thermocycler (PTC-100™, MJ Research, Watertown, MASS, USA) as follows: 1 cycle at 95°C x 5 min for initial denaturation, annealing at 53°C x 2 min, chain elongation at 72°C x 2 min, and 39 subsequent cycles at 94°C x 1 min for denaturation, annealing at 51°C x 2 min and chain elongation at 72°C x 2 min. A final extension of 72°C for 10 min followed the last

cycle. As a positive control for the PCR protocol of HPV-16 and HPV-18 genotypes, serial 1:10 dilutions with 5 μ l SiHa and HeLa culture cells was performed in each experiment. For general HPV detection, a dilution mixture with both positive controls was realized. Positive controls always produced amplicons of the correct size. As a negative control, sterile water was utilized in place of the 5- μ l DNA sample. To avoid false-positive results, all known precautions to avoid a PCR product carry-over and sample-to-sample contamination were rigorously carried out. Different steps of the PCR procedure were performed in separate rooms with different pipettes. None of the negative control samples were positive in any of the HPV assays.

DNA analysis. To characterize the amplified products, the samples were analyzed by electrophoresis in vertical gels of 8% non-denaturing polyacrylamide. They were subjected to electrophoretic conditions of 200 mA constantly for a 2-h period, and were stained with AgNO₃ according to the method reported by Bettini *et al* (26). A 50-bp DNA ladder (Biotools, B&M Labs, Madrid, Spain) was used as size marker.

Statistical analysis. GraphPad Prism 4.0 for Windows (GraphPad Software, San Diego, CA, USA) was used for all statistical analyses. Descriptive statistics were used to summarize the study data. The χ^2 test was performed for statistical comparisons of the categorical variables between groups. Kaplan-Meier curves were used for the graphical representation of survival and the log-rank test was used to

analyze significant differences in survival curve comparisons (27). Analysis was computed by comparing the HPV positive or negative tumors. Survival data were censored for patients that were alive at the last follow-up. In addition, the survival data were censored for those patients with no recurrence of DFS. Statistical significance was defined as a two-tailed P-value ≤ 0.05 .

Results

Patient age varied between 46-90 years (mean, 59). Clinical data from the study population are summarized in Table I.

For each patient, two samples were analyzed, one from the PT and the other from the corresponding MS. The investigated MS samples consisted of 49 tumoral recurrences, 28 LNMs and 10 necropsies.

Internal control amplification with β -globin primers PC03/PC04 showed amplifiable DNA in all 174 paraffin-embedded specimens studied. General amplification with the HPV L1 (GP5+/GP6+) consensus primer pair showed the presence of HPV DNA in 18 of the 174 (10.4%) specimens and in 17 of the 87 (19.5%) studied patients (Table II). The HPV-positive control was amplified in all reactions.

There was HPV DNA positivity in 10 of the 87 (11.5%) PT-analyzed samples. In the MSs, HPV DNA was identified in 8 of 87 (9.2%) paraffin-embedded OSCC specimens; 4 (4.6%) were tumoral recurrences, 3 (3.5%) LNM and 1 (1.1%)

necropsy. Of the MSs, 7 (8.1%) were without viral detection in their corresponding PTs, and only one patient demonstrated HPV DNA positivity in both samples (Table II). The tongue was the most prevalent anatomical site for HPV DNA positivity followed by the hard palate, which had 6 (33.3%) and 4 (22.2%) of the 18 positive paraffin-embedded specimens, respectively.

The presence of HPV-16 and -18 genotypes was detected in 4 (22.2%) and 3 (16.7%) of the 18 OSCC HPV positive-testing paraffin-embedded specimens, respectively. Both genotypes were found in 6 (33.3%) samples and the HPV genotype was not identified in 5 (27.8%) of them (Table II).

The HPV DNA-positive OSCC patients consisted of 13 males and 4 females, with a male-female ratio of 3.25:1. However, the HPV positivity rate of males was lower than that of females (17.8 vs. 28.6%). Both the investigated samples from one female patient were positive (PT and MS), and four HPV-positive samples from females were located in the tongue (Table II). However, no significant differences were found when HPV infection was analyzed according to gender (Fig. 1, $P=0.460$) or age (Fig. 2, $P=0.418$).

Histological differentiation was not influenced by the presence of HPV DNA ($P=0.296$, Table III), although the majority (12-66.7%) of the 18 HPV-positive specimens were considered histologically well-differentiated (61.1%). HPV-positive samples were significantly more frequent among non-smoking patients ($P=0.013$, Table IV).

^aHistological differentiation according to the World Health Organization classification (22).

The follow-up period ranged from 6 to 118 months (median 20). There were 33 (37.9%) deaths, 9 in HPV-positive and 24 in HPV-negative patients. The median DFS was 13 months and the 5-year OS 28.6%. In Kaplan-Meier analyses, even though HPV-negative patients had better survival in the OS and DFS curves, no significant results were found in the survival curve comparisons (OS, $P=0.859$; DFS, $P=0.254$). HPV-negative patients had a 37-month median survival and a 5-year OS of 29.9%. For HPV-positive patients, median survival was 35 months and 5-year OS 28.5%. Curves for OS and DFS according to HPV DNA status are presented in Figs. 3 and 4, respectively.

Discussion

The actual prevalence of HPV DNA in OSCC and its role as a possible oncogenic agent are still controversial. Some authors have pointed out that the occasional finding of HPV DNA in OSCC specimens might not result from viral infection but rather from an incidental HPV colonization of the oral mucosa, and that high infection rates with the presence of more than one HPV genotype could be due to the occurrence of opportunistic and cumulative infection by it and other pathological agents

in the tumoral lesion (28,29). Moreover, high HPV prevalence rates obtained in some studies may have been influenced by false-positive results that led to overestimated infection rates and instigated confusion regarding the etiologic role of HPV in OSCC (1,17,28).

In the 174 OSCC samples tested in our study, the overall positivity rate of 18 (10.4%) is very close to the results reported by Dahlgren *et al* (7), who studied tongue OSCC (10.9%). However, their study included mobile and base tongue samples and, considering only the mobile tongue results, our HPV-positive rate (22.7 vs. 2.4%) is higher. Our HPV-positive rate is also higher than results found by Kantola *et al* (30), who detected no HPV presence in the 105 (paraffin-embedded) mobile tongue tumors they analyzed.

Few studies have investigated HPV continuity or reinfection in the tumoral recurrence, LNM or necropsies samples of OSCC (11,31). Similar to results reported by Howell and Gallant (11), we detected HPV-16 in both the PT and MS of only one OSCC case while, in 7 cases, HPV DNA could only be detected in the MS and not in the PT. These findings could suggest that HPV presence is transitory in OSCC progression.

Several reports have proposed a potential role for HPV genotypes associated with a high risk of cervical cancer in the malignant transformation of oral mucosa stem cells (32,33). However, the HPV-16 and -18 individual frequencies we discovered (22.2 and 16.7%, respectively), as well as the dual infection frequency (33.3%), were lower than those reported in other investigations (3,34).

In 5 of the 18 (27.8%) tumoral samples, the HPV genotype was not identified. Some authors have previously observed that there is no set of primers that can detect all HPV genotypes, and that most HPV consensus primers are primarily designed to detect the HPV genotypes that are common in cervical samples (35).

Contrary to Cruz *et al* (36), but in accordance with others (34,37), the HPV-positive sample distribution showed no significant difference in histological differentiation grade classification.

Despite our having the largest number of OSCC male patients of all the studies that have been conducted, the result of a higher rate of HPV-positive occurrence in OSCC females (28.6%) than males has never been seen before. However, this inverse difference did not reach statistical significance. Most other investigations also included more males than females, but had less women with HPV-positive tumors (34,38,39). Moreover, in contrast to some studies (1,36,37), a significant HPV prevalence in males or patients less than 60 years old could not be detected in our investigation.

The association between HPV status and tobacco consumption reached statistical significance, confirming previous studies that showed HPV infection to be more frequent in non-smokers (40,41). This may occur due to a protective effect of the increased keratinization of the normally parakeratinized mucosal surfaces in smoking patients (42).

Several studies have examined the association between HPV detection in oral and oropharyngeal squamous cell carcinomas and patient survival. However, the results of these investigations have led to different conclusions. A few studies found that HPV-infected OSCC patients have better survival than those with HPV-negative tumors (38,39,43).

Ritchie *et al* described a possible interaction between HPV infection and gender on survival in oral and oropharyngeal cancers (39). Due to the small number of HPV-positive samples in our study, it was not possible to research this gender association.

We found reduced OS rates and no significant difference in the survival curves (DFS and OS) of HPV-positive and -negative samples. Our results demonstrate a smaller discrepancy between the 5-year OS rates of HPV-positive and -negative tumors (28.5 and 29.9%, respectively) than those of Ritchie *et al* (39), which indicated a significant difference of 71 and 49% in HPV-positive and -negative tumors, respectively.

The reported frequency of HPV DNA detection varies considerably between studies. This may be due to variation in the preservation, preparation and storage of the samples, different detection methods, distinct study populations and mixed anatomical areas. In some reports, it is not clear whether the analyzed samples originate from the oral (mobile) tongue or from the base of the tongue, which is part of the oropharynx. Since oropharyngeal tumors have a different prognosis and are more likely to be HPV positive than tumors from the oral cavity, tumor localization is a fundamental survival factor in OSCC studies. This study addressed the limitations of some previous studies by focusing only on oral cavity carcinomas.

Many OSCC patients die of second PTs of the upper aerodigestive tract. Patients with HPV-associated OSCC are less prone to traditional risk factors, such as tobacco, and it is less probable that they will develop a second PT, resulting in a better prognosis for the disease (5,44). The large number of non-smoking HPV-positive patients as seen in our results, might explain the better prognosis for patients with HPV infection. The small number of non-smoking patients with OSCC makes this research more difficult, resulting in few studies that describe the possible interaction between smoking and HPV infection. Additional studies are required to compare HPV status and survival among non-smokers in order to further support the notion of a favorable prognosis found in other studies. We were unable to make this comparison due to the small number of non-smoking patients.

Although we cannot rule out a possible transient role for HPV in the induction of OSCC, we think that the occasional detection of HPV in OSCC resulting from the incidental colonization of OSCC lesions might reflect the true involvement of HPV in most investigations. We suggest that other methodologies should be utilized and population studies should be performed to confirm our results. The few studied OSCC cases with detectable HPV suggest that this virus does not have the same etiological influence as tobacco consumption in these patients. However, a relative HPV contribution to oral carcinogenesis may occur in a subgroup of patients, mainly in areas where tobacco use is less common.
