Abstract. In several cancers, the acidic microenvironment of cancer cells has been implicated in enhanced malignancy and metastasis. In the present study, it was observed that gastric cancer cell lines, SNU601 and AGS, exposed to an acidic medium had increased invasiveness, as assessed using Matrigel-coated Transwell analysis. The factors regulating such acidity-mediated enhancement of invasiveness were investigated and it was revealed that a low-pH environment markedly increased kallikrein-related peptidase 7 (KLK7) and kallikrein-related peptidase 8 (KLK8) expression. Gene silencing assays confirmed that these peptidases were involved in acidity-promoted invasion. Acidic conditions also increased the expression of cyclooxygenases (COX), key regulatory enzymes in the catalytic pathway of prostaglandin production. Notably, these enzymes appeared to be involved in the acidity-mediated expression of KLK7 and KLK8, as revealed using COX inhibitors. Therefore, it was indicated that tumor invasion enhancement by extracellular acidity is regulated at least in part through the induction of the COX/KLK7 and KLK8 axis in gastric cancer cells.

Introduction

The ability to invade tissues and metastasize is the major cause of cancer mortality (1-3). Although advances in understanding cancer invasion and metastasis have revealed several important potential molecular targets, treatment of cancer metastasis is still limited. Metastasis occurs through a series of interrelated steps of cell detachment, migration, invasion, and adhesion, and is controlled by multiple biochemical and signaling pathways. Metastatic processes have recently been suggested to be significantly influenced by microenvironmental factors, such as oxygen levels or pH.

Recent evidence has revealed that the pH of the microenvironment of solid tumors is relatively acidic due to the accumulation of lactic acid as a result of active aerobic and anaerobic glycolysis (4). Such environmental acidity has been reported to enhance malignant transformation, invasion, and metastasis of several cancer cells. Exposure of melanoma cells to acidic pH induced acid-resistant and invasive phenotypes (5). Acidic environments also enhanced local invasion and metastasis of human colon cancer cells (6,7). In addition, acidity promoted the malignant progression, induction of cancer stem cell phenotypes, and the epithelial-mesenchymal transition in glioma and melanoma cells (8,9). Although recent studies have revealed that acidity upregulated transcription factors such as NF-κB and Twist1 and is associated with alterations in adherence junction proteins, including E-cadherin, p120-catenin, and β-catenin, the mechanism by which acidity drives cancer cell invasion is not yet fully understood (8,9).

Currently, multiple lines of evidence have revealed that proteases are involved in cancer invasion and metastasis due to their ability to cleave extracellular matrix components, adhesion molecules, and cytokines (10). Kallikrein-related peptidases (KLKs) are a subgroup of chymotrypsin-like serine proteases composed of fifteen homologous members, KLKs 1-15. KLKs regulate diverse essential physiological processes, and certain KLK members act as signaling regulators that control cell functions through specific membrane receptors, the protease-activated receptors (PARs) (11-14). Notably, several members have been reported to be overexpressed, and therefore, could serve as potential biomarkers for diagnosis and prognosis, in various cancers including ovarian, prostate, pancreatic and cervical cancer (15,16). Therefore, KLKs have been extensively studied for their use as cancer therapeutic targets (17). In the present study, it was revealed that extracellular acidity markedly increased the expression of KLK7 and KLK8 in gastric cancer cell lines and the role of these enzymes in the acidity-mediated invasiveness in these cells was investigated.
Materials and methods

Cell culture and pH adjustment. SNU-601 and AGS human gastric cancer (GC) cells were obtained from the Korean Cell Line Bank and the American Type Culture Collection, respectively. Cells were cultured in RPMI-1640 medium (Invitrogen; Thermo Fisher Scientific, Inc.) supplemented with 10% (v/v) fetal bovine serum and 1% PS at 37°C in an atmosphere containing 5% CO₂. For preparation of acidic pH medium, pH 7.4 RPMI-1640 medium containing 1% FBS medium was prepared, and then adjusted to pH 6.5 or 6.2 by adding 5M HCl solution. Sulindac and NS398 were purchased from Calbiochem; EMD Millipore. For Cox inhibition, cells were exposed to pH 7.4, 6.5 and 6.2 in the presence of 20 µM NS398 or 100 µM sulindac for 72 h, and the treated cells were harvested for western blot analysis or real-time PCR assay.

Invasion assay. To assay cell invasiveness, Matrigel-coated Transwell chambers (Costar; Corning Incorporated) were used. Cells in the logarithmic phase were incubated in RPMI-1640 medium containing 1% FBS, adjusted to pH 7.4, 6.5 or 6.2, for 72 h, after which the number of viable cells that corresponded to the equal absorbance detected in a standard curve for a viability assay were obtained from each pH condition and suspended in 1% FBS/RPMI-1640 medium adjusted to each pH condition (pH 7.4, 6.5 or 6.2). Then ~200 µl of the cell suspension was added to the upper portion of the insert, and medium containing 5% FBS was added to the lower portion of the insert. After 8 h (for AGS) and 18 h (for SNU601) of incubation at 37°C in 5% CO₂, noninvasive cells were removed from the upper surface of the Transwell membrane with a cotton swab, and the invaded cells on the lower layer surface were fixed by 4% formaldehyde for 15 at RT and stained with 0.5% crystal violet solution for 10 min RT. The numbers of invaded cells were counted under high-power magnification (x200) or the images were obtained by image analysis software (analysis FIVE; Olympus Corporation).

Before the invasion assay, a standard curve for viability in each pH medium was prepared since exposure to acidic pH medium decreased the number of viable cells. The number of viable cells was determined as follows: Cells cultured for 3 days at each pH were trypsinized, resuspended in normal pH medium and further incubated for the time required for invasion measurement, and a standard curve for viability was prepared using an MTT assay. Following MTT incubation, the purple formazan crystals were dissolved using dimethyl sulfoxide and viability was subsequently analyzed at a wavelength of 595 nm. Based on these survival curves, the number of cells corresponding to the same absorbance was calculated and used for this assay.

Western blot analysis. Treated cells were lysed in either a whole-cell lysis buffer (50 mM Heps, 150 mM NaCl, 1% Triton X-100, 5 mM EGTA, protease inhibitor cocktail). Protein determination was performed by BCA method. Equal amounts of protein extracts (50 µg of protein per lane) were electrophoretically separated using 10-12% SDS-PAGE and transferred to a nitrocellulose membrane using a standard technique. Blocking was performed by incubation in 3% skim milk/0.1% Tween Tris-buffered saline for 30 min at 4°C. Antibodies were used to probe for KLK7 (dilution 1:500; cat. no. sc-514447; Santa Cruz Biotechnology, Inc.), cyclooxygenase (COX)2 (dilution 1:200; cat. no. 160112; Cayman Chemical), KLK8 (dilution 1:1,000; cat. no. ab150395; Abcam), COX1 (dilution 1:500; cat. no. ab695; Abcam) and α-tubulin (dilution 1:2,000; clone no. B-5-1-2; cat. no. 32-2500; Invitrogen; Thermo Fisher Scientific, Inc.). The secondary antibodies used were: Anti-rabbit HRP (dilution 1:2,500; cat. no. sc-2030; Santa Cruz Biotechnology, Inc.), anti-mouse HRP (dilution 1:2,500; cat. no. sc-2031; Santa Cruz Biotechnology, Inc.) were used. Anti-a-tubulin was used as a loading control. Protein bands were visualized with the Super Signal West Pico chemiluminescence kit (Pierce Biotechnology; Thermo Fisher Scientific, Inc.). Protein blots were quantified using Alpha Ease FC software version 4.0 (Alpha Innotech). Signals were acquired using an Image Station 4000MM image analyzer (Kodak).

RNA interference (RNAi). For the RNAi experiment, siRNAs of KLK7, KLK8, COX1 and COX2, and a scrambled siRNA control were purchased from Bioneer Corporation. Cells were individually transfected with siRNA oligonucleotides using an Amazatm Transfection System (Lonza Bioscience) and grown for 24 h prior to exposure to acidic pH medium.

Real-time reverse transcription-polymerase chain reaction. Real-time PCR was performed with the Light Cycler 2.0 (Roche Diagnostics) using the Fast Start DNA Master SYBR-Green I Kit (Roche Diagnostics). For verification of the correct amplification product, PCR products were analyzed on a 2% agarose gel stained with ethidium bromide. The sequences of the primers were designed as follows: For β-actin, 5'-GACTATGACTTTAATGGGCTA-3' and 5'-GCCATTACCTCTCAAAGTG-3', for COX1, 5'-GGCGGCTACATTCTTCAC-3' and 5'-CCTCATGTGCTGCTCTTTCG-3', for COX2, 5'-AAACACACAGAGATGCGCA-3' and 5'-GGTTGAAATTCCAGCGACAATGC-3', Primers of KLK7 (product no. P109693), KLK8 (product no. P178536), matrix metalloproteinase 7 (MMP7) (product no. P310408) and matrix metalloproteinase 9 (MMP9) (product no. P323207) were purchased from Bioneer Corporation. PCR was conducted at 95°C for 10 min, followed by 45 cycles of 95°C for 15 sec, 60°C for 5 sec, and 72°C for 7 sec. Melt curve analysis was performed to confirm that a single product was present. Negative controls without template were included in each run. Data were analyzed using Light Cycler software version 4.0 (Roche Diagnostics). The 2−ΔΔCq method was used for analysis of relative gene expression (18).

Detection of KLKs in cell culture supernatants. Cells were incubated in RPMI-1640 medium containing 1% FBS, adjusted to pH 7.4, 6.5 or 6.2, for 72 h, after which culture medium was obtained and release of KLK7 and KLK8 from cells was assessed using a specific sandwich-type ELISA assay according to established procedures with some modifications (19). Briefly, 96-well polystyrene plates were coated with 500 ng/well of a specific capture antibody. After overnight incubation, the plates were washed and 50 µl of culture supernatant or standard and an equal volume of assay buffer were added and incubated for 2 h. Plates were washed and biotinylated antibodies were subsequently added. After
incubation and washing, alkaline phosphatase-conjugated streptavidin was added. Then, diflunisal phosphate stock solution and terbium-based detection solution were added, and fluorescence was assessed with a fluorometer (Perkin-Elmer). Calibration and data reduction were performed automatically.

Statistical analysis. All numerical data are presented as the mean ± SE of at least three independent experiments. Student’s t-test was used for simple comparisons, and one-way ANOVA with Tukey’s post hoc test was applied for multiple comparisons. P<0.05 was considered to indicate a statistically significant difference.

Results

Incubation in acidic culture medium increases GC cell invasion. Previous research has revealed that extracellular acidity induces tumor growth, invasion, and metastasis. It was observed that incubation of gastric cancer cell lines AGS and SNU601 in an acidic pH medium triggered increased invasion of the cells compared to those cultured in normal-pH medium. To detect invasiveness, cells were cultured in culture medium adjusted to pH 7.4, 6.5 or 6.2 for 3 h, then the same number of viable cells were obtained and added onto the upper portion of Transwell plates which were coated with Matrigel. After 8 h for AGS and 24 h for SNU601 cells, the number of cells that invaded to the lower chamber was counted. The results revealed that the number of cells invading to the lower portion of the Transwell plates increased in the acidic environment (Fig. 1A-D). In addition, the mRNA levels of proteolytic enzymes MMP7 and MMP9, which are known to be involved in cancer cell invasion, were increased, as assessed by real-time PCR (Fig. 1E-H).

Cells cultured in acidic medium increase expression of KL7 and KL8. Proteases play crucial roles in cancer invasion and metastasis due to their proteolytic activity to cleave extracellular matrix and adhesion molecules. Although MMPs are known to be essential proteases mediating cell invasion, a possible involvement of other proteases in cancer cell invasion under an acidic environment was explored. Notably, it was revealed that the levels of KL7 and KL8 were significantly increased in acidic culture conditions. Acidic pH culture conditions significantly increased the mRNA levels of KL7 and KL8 in both gastric cancer cell lines (Fig. 2A-H). To assess whether increased mRNAs of KL7 and KL8 led to increased protein levels, immunoblot assays were performed using cell lysates. When the cells were incubated in acidic medium, the protein levels of KL8 increased but those of KL7 decreased (Fig. 2I and J). Since KLs are proteases mainly secreted into the extracellular space, the protein levels of KL7 and KL8 released into the medium were also examined using an ELISA assay. As the pH decreased, the amounts of KL7 and KL8 proteins released into the medium significantly increased (Fig. 2K and L). Thus, acidity induced the expression and secretion of KL7 and KL8.

Elevation of KL7 and KL8 is linked to acidity-induced invasion. Since KL family members have been revealed
to be involved in malignant phenotypes of certain cancers, it was hypothesized that increased KLK7 and KLK8 in acidic environments would play a role in the acidity-mediated invasion of these cancer cells. To examine this, cells treated with siRNAs specifically silencing KLK7 or KLK8 were exposed to acidic medium. Cells in which KLK7 or KLK8 were silenced exhibited low invasiveness after incubation in acidic (pH 6.5) culture medium (Fig. 3A and B). The silencing efficiency of the KLK7 and KLK8 siRNAs was confirmed by decreased protein levels (Fig. 3C and D). Thus, increased expression of KLK7 and KLK8 appears to be linked to the enhanced invasiveness of gastric cancer cells.
Induction of COX1 and COX2 is involved in acidity-mediated KLK7 and KLK8 expression. To understand the regulatory mechanisms involved in acidity-mediated KLK7 and KLK8 expression, potential upstream regulators were examined. Previously, acidity was revealed to stimulate inflammatory responses via the cyclooxygenase (COX) pathway. Consistent with a previous study, acidic culture conditions elevated mRNA and protein levels of COX2 in both GC cell lines (20). In addition, the mRNA and protein expression of COX1, a constitutive isoform, increased (Fig. 4). Thus, the role of COXs in KLK induction was examined by assessing the effect of COX inhibitors on the expression of KLK7 and KLK8. Upon exposure to sulindac, a broad COX inhibitor, acidity-induced mRNA expression of KLK7 and KLK8 was reduced. In contrast, exposure to selective COX2 inhibitor NS398 had little effect on the level of these peptidases (Fig. 5A-D). This indicated that the COX pathway is involved in acidity-induced KLK7 and KLK8 expression, and that COX1 plays a more important role than COX2 in the expression of KLK7 and KLK8. To confirm this, cells transfected with siRNAs silencing COX1 or COX2...
Figure 5. General COX inhibitor, sulindac reduces acidity-induced KLK7 and KLK8 expression, and invasion of GC cells. (A-D) Cells were exposed to pH 7.4, 6.5 and 6.2 in the absence or presence of 20 µM NS398 or 100 µM sulindac for 72 h, and the mRNA expression of the genes encoding KLK7 and KLK8 was analyzed by real-time PCR. (E and F) Cells exposed to pH 6.5 in the absence or presence of 20 µM NS398 or 100 µM sulindac for 72 h was counted and equal amounts of viable cells were placed into the inner wells of Matrigel-coated Transwell plates, and the invasive ability was assessed by counting cells invading through the membrane after further incubation of 18 h for SNU601 and 8 h for AGS cells. *P<0.05 vs. vehicle. COX, cyclooxygenase; KLK7, kallikrein-related peptidase 7; KLK8, kallikrein-related peptidase 8.

Discussion

Previously, we reported that acidic culture conditions are associated with a decrease in cell growth and an increase in chemoresistance of gastric cancer cells (20). In the present study, it was demonstrated that gastric cancer cells surviving in low-pH environments (pH 6.5 and 6.2) were more invasive than cells cultured at normal pH, in line with previous studies revealing that extracellular acidity can enhance carcinogenesis and cancer progression by promoting local invasion and metastasis of the tumor (6,7). Although, mild acidic pH ranges were selected to focus on the acidic pH that is formed inside solid cancer tissue in this study, in future
studies the effect of lower pH, such as that in the stomach, will be investigated.

An acidic environment can affect the expression of multiple genes in tumor cells. In searching for factors contributing to acidity-mediated invasion, it was revealed that the expression of certain proteases was induced by acidity. Evidence collected over the past several years has revealed that proteases play an essential role in invasion and metastasis of tumor cells because they break bonds with surrounding cells or tissues and degrade the extracellular matrix, thereby allowing tumor cells to penetrate through physical barriers (21). Thus far, various proteases, including cathepsin B, cathepsin D, the urokinase-type plasminogen activator, and several matrix metalloproteases, have been revealed to be involved in tumor invasion and metastasis (22,23). In the present study, it was revealed that GC cells exposed to acidic culture medium had markedly increased expression of KLK family members KLK7 and KLK8, and a considerable amount of these peptidases was secreted into extracellular space. Through siRNA-based gene silencing, it was revealed that these peptidases are involved in the promotion of acidity-mediated migration and invasion.

KLK family members are known to be involved in the regulation of various physiological and pathological processes in human tissues, and certain KLKs play roles in releasing cell-cell adhesion through proteolytic cleavage of junctional proteins, such as desmosomal cadherins (24). Alteration of KLK7 levels is known to be linked to several skin disorders, including dermatitis, psoriasis, and Netherton syndrome (25-27). Notably, overexpression of KLKs is often linked to aggressive phenotypes in multiple cancers. A recent study revealed that an increased KLK7 level was linked to increased proliferation of colorectal cancer cells and associated with poor prognosis or short survival in colon, ovarian and pancreatic cancers (28-30). Furthermore, KLK7 has been described as being potentially involved in metastasis in colorectal and pancreatic cancer, and melanoma (31-34). KLK8, found in numerous normal tissues as well as in body fluids, is also implicated in a variety of malignant tumors, including ovarian, cervical, salivary gland, and lung cancers when aberrantly expressed (35-39). In addition, overexpression of KLK8 is considered to be a potential independent prognostic indicator for CRC. The study on KLK7 and KLK8 is still in the beginning step, and to the best of our knowledge, this is the first study revealing that KLK7 and KLK8 are involved in acidity-mediated gastric cancer cell invasion. Although the link between gastric cancer and KLK7 and KLK8 has not been reported, a previous study indirectly supported the tumor promoting role of KLK7 in gastric cancer, in which inhibition of the growth of transplanted gastric cancer by cisplatin was accompanied by reduction of KLK7 expression (40).

Nevertheless, some studies have demonstrated the opposite effect of KLK7 and KLK8 on cancer. For example, high levels of KLK7 were linked to decreased proliferation in melanoma and a favorable prognosis in melanoma patients (41,42). Increased KLK8 was associated with either a favorable prognosis or no effect on patient outcomes in ovarian cancer (43,44). Since the invasion process requires protease activity to cleave tumor cells from surrounding cells or the extracellular matrix, regulation of cancer cell invasion by KLK may be directly linked to the action of the downstream substrates of KLKs, such as E-cadherin, fibronectin, laminin, IGFBP3, and midkine. Thus, these discrepancies are likely explained by the dominant substrates available for KLK7 or KLK8 in specific environments, although the exact roles of KLK7 and KLK8 in specific cancer tissues and pH environments requires further investigation through in vivo studies.

Although various important functions of KLKs have been identified, regulatory mechanisms involving KLK expression have not yet been elucidated. In the present study, it was observed that acidic pH conditions increased the expression
of COX1 and COX2 in GC cells. It was hypothesized that the acidity would regulate KLK7 and KLK8-mediated invasiveness through COX induction. Previously, acidity-induced COX2 expression was also observed in oral cells (45). COX is well established to play a crucial role in a wide range of inflammatory responses, in which acidity also plays roles. Extracellular acidity triggers activation of immune responses in multiple immune cells, endothelial cells, and fibroblasts (46-48), and many chronic inflammatory diseases involve acidic pH regions (49). Notably, the inflammatory response acts as a critical factor affecting carcinogenesis and cancer progression. Therefore, the present study may provide an explanation for the induction of inflammatory responses and the increase in tumor invasion in acidic environments, and in further study, a more specific link between acidity-mediated inflammation and tumor invasiveness is under investigation by evaluating the expression of inflammatory-related genes including interleukin 8 and c-Myc.

In the present study, it was demonstrated that an acidic environment could increase COX1-regulated KLK7 and KLK8 expression, and this event contributed to the acidity-induced promotion of GC cell invasion. This study indicates KLK7 and KLK8 as potential targets for anticancer therapies in acidic tumor microenvironments.
