Abstract. Zidovudine (AZT) is an antiretroviral drug widely used in the treatment of human immunodeficiency virus (HIV)-infected patients, whose prolonged administration was found to cause toxic lesions in cardiomyocytes in humans and experimental animals. Alterations in adrenocortical secretion were frequently observed in HIV patients, but it is not clear whether medication is involved in the production of these complications. Hence, we studied in vivo and in vitro, the effects of AZT on the rat adrenal cortex. The prolonged AZT administration (100 mg/kg per day for 4 months) did not cause overt qualitative morphological alterations of adrenocortical cells, which, however, underwent a net hypertrophy. Hypertrophy is associated with increases in the volume and surface area per cell of the mitochondrial compartment and smooth endoplasmic reticulum (where the enzymes of steroid synthesis are located), and a marked decrease in the volume of the lipid-droplet compartment (where cholesterol and its esters, the precursors of steroid hormones, are stored). AZT chronic treatment induced rises in the plasma concentrations of aldosterone and corticosterone, and in the basal and ACTH-stimulated in vitro secretion of these hormones from adrenal slices. The 24-h exposure to AZT (10^{-5} M) did not significantly affect either secretory activity or proliferation and apoptotic rates of cultured rat adrenocortical cells. Taken together, these findings suggest that AZT chronic treatment enhances the growth and steroidogenic capacity of rat adrenal cortex, probably by activating the central branch of the hypothalamic-pituitary-adrenal axis. The toxic activity of AZT is thought to depend on increased production of ROS. On these grounds, it is likely that the lack of toxic effect of AZT on adrenocortical cells is due to their very elevated content in vitamin C, which prevents the deleterious effect of the AZT-induced increase in intracellular ROS production.

Introduction

Adrenal insufficiency is a well known complication in advanced stages of human immunodeficiency virus (HIV) infection, and the prolonged medication is suspected to be involved in its pathogenesis (reviewed in refs. 1-3). In fact, ketoconazole inhibits adrenal steroidogenesis, rifampin enhances cortisol metabolism and megestrol acetate suppresses pituitary ACTH secretion. In contrast, early stages of HIV infection are frequently associated with a marked rise in both basal and ACTH-stimulated cortisol blood levels (3-6). However, it is not known whether antiretroviral therapy is involved, at least in part, in the production of hypercortisolemia.

Zidovudine (AZT) is a widely used drug in the treatment of patients with acquired immune deficiency syndrome (AIDS) (7). Several studies have shown that prolonged administration of AZT induces heart toxicity both in humans and experimental animals, mainly due to mitochondrial dysfunctions in myocardiocytes (8-12), but the effects of this drug on adrenal function have not yet been studied. Therefore, it seems important to investigate, in vivo and in vitro, the effects of AZT on the structure and function of the adrenal cortex in the rat, in order to evaluate the possibility that adrenal dysfunction occurring in HIV patients is, at least partly, a side-effect of the therapy with this antiretroviral drug.

Materials and methods

Reagents and animals. AZT was purchased from Glaxo Smith Kline (Verona, Italy), ACTH from Phoenix Pharmaceuticals (Belmont, CA) and medium 199 from Difco (Detroit, MI). Pure idrosoluble 3'-azido-3'-deoxthymidine (AZT), doxorubicin, 5-bromo-2'-deoxyuridine (BrdU), 4',6'-diamine-2'-phenilindole (DAPI), Dulbecco’s modified Eagle’s medium (DMEM), fetal calf serum (FCS), bovine serum albumin (BSA), and all other laboratory reagents were provided by Sigma-Aldrich Corporation (St. Louis, MO). Wistar Kyoto male rats were obtained from Charles-River (Como, Italy).
Study protocol. Sixteen rats (weighing 300-350 g at the beginning of treatment) were housed in temperature- and humidity-controlled conditions, exposed to a 12-h light/dark cycle, and given tap water ad libitum and standard chow. Rats were divided into two equal groups. One group was treated with AZT (100 mg/kg per day) dissolved in drinking water (11,12) for 4 months, and the other group was untreated and served as a control. Animals were decapitated at 11:00 a.m., and their trunk blood was collected with apoprotin (70 mg/ml) and EDTA (1 mg/ml); plasma was separated and stored at -80˚C. Adrenal glands were removed and freed of pericapsular fat; the left gland was processed for light and electron microscopy, and the right one was immediately used for in vitro studies. Adrenals of other 12 untreated rats were used to obtain primary adrenocortical cell cultures. The study protocol was approved by the local Ethics Committee for Biomedical Studies, and the investigation was carried out according to the Guide for the Care and Use of Laboratory Animals (US National Institutes of Health; publication No. 58, revised 1996).

Incubation of adrenal slices. Right adrenals from control and AZT-treated rats were halved, and each half was cut into thick slices (13). Slices were placed in medium 199 and Krebs-Ringer bicarbonate buffer with 0.2% glucose, containing 5 mg/ml BSA. The samples were incubated (4-5 mg/ml) in the presence or absence of 10^-9 M ACTH. The incubation was carried out for 180 min in a shaking bath at 37˚C in an atmosphere of 95% air and 5% CO2. At the end of the experiment, the incubation medium was collected and kept at -80˚C.

In vitro culture. Adrenals from untreated rats were halved, enucleated to remove medulla and chopped into small fragments under sterile conditions. Dispersed adrenocortical cells were obtained by sequential enzymatic digestion and mechanical disaggregation (14). Dispersed cells were seeded at density of 2x10^4 cells/cm^2 in 24-well polystirene plates, and cultured for 72 h at 37˚C in DMEM (added to 1.125 g/l sodium bicarbonate, 10% FCS, 100 U/ml penicillin and 100 μg/ml streptomycin) in an atmosphere of 95% air and 5% CO2, medium was changed every 12 h (14,15). At day 3 of culture, cells were incubated for 24 h with AZT (10^-5 M), ACTH (10^-9 M) or doxorubicin (10^-6 M). Control cultures were incubated without chemicals. Medium was collected and stored at -80˚C. Some culture dishes had 10^-5 M BrdU in the medium during the last 12 h of incubation.

Hormone assay. Aldosterone and corticosterone plasma concentrations were measured by RIA, using commercial kits (Active Aldosterone and Rat Corticosterone RIAs, Diagnostic Systems Laboratories, Webster, TX ). The hormone concentrations in the incubation media were assayed by quantitative HPLC, as previously detailed (16-18).

Cell proliferation and apoptosis. Proliferating cells were identified by using the BrdU Labeling and Detection Kit I, and apoptotic cells by the Cell Death Detection Kit (Roche Diagnostics, Mannheim, Germany), according to the manufacturer's directions. Nuclei were stained with DAPI, and BrdU- and TUNEL-positive cells were detected by...
double-fluorescence microscopy in a Leica DM-IRE2 inverted microscope. Proliferation and apoptotic rates were estimated by computer-assisted image analysis as the ratio between the number of BrdU- or TUNEL-positive nuclei and that of DAPI-stained nuclei (19-21).

Light and electron microscopy, and morphometry. Left adrenals of control and AZT-treated rats were halved. One half was fixed in Bouin solution overnight, embedded in paraffin and serially cut at a thickness of 6 μm (17). Sliced pieces of the other half were fixed in 3% glutaraldehyde, post-fixed in 1% osmium tetroxide, and embedded in epon (17,22). Thick (0.5 μm) and thin (60-70 nm) sections were cut with a LKB Supernova Ultrotome (Reichert-Jung, Vienna, Austria). Thin sections were counterstained with lead hydroxide, and examined and photographed in a Hitachi H-300 electron microscope. The volumes of zona glomerulosa (ZG) and zona fasciculata (ZF), and the number and volume of their parenchymal cells, as well as the volume of nuclei were determined on light micrographs of paraffin and thick epon sections, as previously detailed (23). On the electron micrographs of ZG and ZF cells, the volume of the mitochondrial and lipid-droplet compartments, and the surface area per cell of mitochondrial cristae and smooth endoplasmic reticulum (SER) were evaluated by conventional stereological techniques (23).

Statistics. The data obtained were averaged per experimental group, and SD or SEM were calculated. The statistical comparison was carried out by ANOVA, followed by Duncan's multiple range test.

Results

Electron microscopy showed that AZT chronic administration did not produce appreciable qualitative alterations of rat adrenal morphologic features (Fig. 1). However, morphometry demonstrated that AZT caused an increase in the volume of ZG and ZF cells, and their nuclei without significantly affecting the volume of zones and the number of parenchymal cells (Table I). ZG and ZF cell hypertrophy was associated with sizeable increases in the volume of the mitochondrial compartment and in the surface area per cell of mitochondrial cristae and SER membranes. Conversely, the volume of the lipid-droplet compartment underwent a marked reduction (Table II; Fig. 1).

Figure 2. Effect of prolonged AZT admistration on the plasma concentration of aldosterone and corticosterone. Bars are means ±SEM (n=8). *P<0.05 from the respective control group.
AZT-treated rats were significantly higher than that of controls (Fig. 3).

As expected, adrenocortical-cell cultures exhibited a clearcut secretory response to ACTH (Fig. 4), and doxorubicin decreased the number of BrdU-positive cells and increased that of TUNEL-positive cells (Figs. 5 and 6). The 24-h exposure to AZT neither affected aldosterone and corticosterone secretion from cultured cells nor did it alter their proliferation and apoptotic indexes (Figs. 4-6).

Discussion

Our present study provides the first evidence that the prolonged treatment with AZT enhances the growth and secretory capacity of the rat adrenal cortex. This contention is based on both morphological and functional findings.

AZT treatment induces the hypertrophy of both ZG and ZF cells, which is coupled with increases in the volume of the mitochondrial compartment and SER. These morphologic data accord well with the rise in the blood levels of aldosterone and corticosterone, as well as with the enhancement of basal and ACTH-stimulated secretion of these hormones from adrenal slices containing ZG and ZF. Indeed, the enzymes of steroid synthesis are located in both mitochondria and SER (reviewed in refs. 24, 25), and the changes
concentration of vitamin C in the mammalian body (33), which the adrenal gland is one of the organs with the highest AZT-induced toxic lesions in rat cardiomyocytes (10,12). The treatment with the anti-oxidant vitamin C is able to prevent in the ROS production (10,12,30-32). Accordingly, the is evidence that cytotoxic effects of AZT depend on the rise accounts for these discrepancies. It is to be recalled that there cultured human placental cells (29,30). It is probable that the apoptosis in the mammalian carcinoma cell line T-47 D and (see Introduction), and decreases proliferation rate and induces apoptosis in the mammalian carcinoma cell line T-47 D and cultured human placental cells (29,30). It is probable that the differences in the susceptibility to AZT among different cells accounts for these discrepancies. It is to be recalled that there is evidence that cytotoxic effects of AZT depend on the rise in the ROS production (10,12,30-32). Accordingly, the treatment with the anti-oxidant vitamin C is able to prevent AZT-induced toxic lesions in rat cardiomyocytes (10,12). The adrenal gland is one of the organs with the highest concentration of vitamin C in the mammalian body (33), which not only is a cofactor required for both steroid-hormone and catecholamine synthesis, but also prevents the destructive effects of lipid peroxidation on adrenocortical mitochondria cytochrome P450 (34-36). Hence, it is possible that the high level of vitamin C preserves adrenocortical cells from the deleterious effects of the AZT-induced increase in intracellular ROS production.
