Abstract. The aim of this study was to determine the expression and function of epithelial membrane protein 1 (EMP1) in gastric carcinoma. Gastric samples were taken from cancer lesions and adjacent normal tissue in gastric cancer patients immediately after endoscopic biopsy. A portion of the sample was either fixed in 4% paraformaldehyde and embedded in paraffin for immunohistochemistry or stored in liquid nitrogen for western blotting. In order to determine protein expression of EMP1 in gastric cancer (n=65) and normal tissue (n=27), semi-quantitative immunohistochemistry and western blotting were utilized. For in vitro studies, the human gastric cancer cell line SGC-7901 was maintained in RPMI-1640 medium supplemented with 10% fetal bovine serum. Recombinant lentivirus mediated overexpression of EMP1 in SGC-7901 cells was quantified with quantitative polymerase chain reaction (qPCR) and western blotting. Control SGC-7901 cells were transfected with an empty vector. To further study the effect of EMP1 overexpression in SGC-7901 cells, cell proliferation, cell apoptosis and migration and invasion assays were conducted. The expression of EMP1 was significantly lower in gastric cancer tissue compared to normal tissue using both immunohistochemistry (41.5 vs. 70.4% of tissues, P<0.05) and western blotting (0.153±0.012 vs. 0.626±0.058, P<0.05). Decreased expression of EMP1 was significantly correlated with tumor invasion, lymph node metastasis, clinical stage and histological grade of patients with gastric cancer (P<0.05). According to Kaplan-Meier analysis, low EMP1 expression correlated significantly with poor overall 5-year survival (47.4 vs. 70.3% survival, P<0.05). SGC-7901 cells transfected with EMP1 had a lower survival fraction, higher cell apoptosis (13.2±1.5% vs. 2.2±0.5%, P<0.05), significant decrease in migration and invasion (157.0±16.0 and 112.0±12.0, respectively vs. 243.0±21.0 and 203.0±19.0, respectively, P<0.05), higher caspase-9 (0.501±0.050 vs. 0.114±0.010, P<0.05) and lower VEGFC protein expression 0.135±0.011 vs. 0.619±0.074, P<0.05) relative to cells not transfected with EMP1. Low EMP1 expression in gastric cancer is associated with increased disease severity, suggesting that EMP1 may be a negative regulator of gastric cancer.

Introduction

The incidence and mortality of gastric cancer have fallen dramatically in USA and elsewhere over the past several decades. Nonetheless, gastric cancer remains a major public health issue as the fourth most common cancer and the second leading cause of cancer death worldwide. For the past few decades, gastric cancer mortality has decreased markedly in most areas of the world (1). However, gastric cancer remains a disease of poor prognosis and high mortality, second only to lung cancer as the leading cause of cancer-related death worldwide. Gastric cancer is a multifactorial disease. The marked geographic variation, time trends and the migratory effect on gastric cancer incidence suggest that environmental or lifestyle factors are major contributors to the etiology of this disease (2). The well-established histopathological factors that influence disease outcome are tumor size, histological type and subtype, the presence of signet ring morphology, the degree of differentiation, the presence of lymphovascular invasion and lymph node involvement (3,4). Further understanding of the molecular mechanisms underlying the pathophysiology of metastatic processes will not only help us to identify those patients at greatest risk of recurrence but also find novel molecular targets for the development of treatment strategies for gastric cancer. A preliminary study on the epithelial membrane protein 1 (EMP1) gene found that EMP1 is closely linked to tumor development and progression (5,6). Activation of the EMP1 gene in particular can prevent tumor proliferation,
and it may be a new target for tumor therapy (7,8). However, to date there is no information available regarding the relationship between EMPI and gastric cancer. We studied EMPI expression in gastric cancer using immunohistochemistry and western blot and analyzed the effect of EMPI overexpression in vitro in the gastric cancer cell line SGC-7901 (9,10).

Materials and methods

Clinical data. All patients enrolled in this study provided informed consent in advance. There were 39 males and 26 females, aged from 21 to 78 years old, with a median age of 54 years. Of the 65 cases of gastric cancer, 31 had T1 and T2 stage cancers and 34 had T3 and T4 stage cancer. Twenty-seven patients presented with lymph node metastasis (N0), whereas 38 presented with identified lymph node involvement (N+). As for the clinical stage, 28 cases had stage I-II gastric cancers and 37 had stage III-IV gastric cancer. Regarding grade of differentiation, 29 had Grade I (well differentiated) tumors and 36 had Grade II or III (moderately to poorly differentiated) tumors. Samples were taken immediately after the endoscopic biopsy, and either fixed in 4% paraformaldehyde solution and embedded in paraffin for immunohistochemistry or stored in liquid nitrogen for western blot analysis.

Cell culture and gene transfection. Human gastric cancer SGC-7901 cells were maintained in RPMI-1640 medium (Gibco BRL, Carlsbad, CA, USA) supplemented with 10% fetal bovine serum (Gibco BRL). Medium was changed every 2-3 days; when the cultures reached confluence, the cells were subcultured with 0.25% trypsin and 1% ethylene diaminetetraacetic acid (EDTA). Cells were tested every 3 months for mycoplasma and mycoplasma removal agent (MRA) (MP Biomedicals Co., Ltd., Shanghai, China) was used to maintain mycoplasma-free cultures. EMPI cDNA was cloned into the BamHI and Ascl sites of the plenti6/V5-DEST vector (Invitrogen, Carlsbad, CA, USA). After amplification and DNA sequence confirmation, this vector was used to overexpress EMPI in SGC-7901 cells. Briefly, SGC-7901 cells were grown and stably transfected with pLenti6-EMPI or plenti6/V5-DEST for control using Lipofectamine 2000 (Invitrogen) and grown in Blasticidin (5 µg/ml)-containing RPMI-1640 medium.

Immunohistochemistry. Immunohistochemistry was performed as previously described (11). Briefly, 4-µm sections were prepared from a paraffin-embedded block and dehydrated, incubated in 3% hydrogen peroxide for 10 min and incubated in trypsin for 20 min. Sections were blocked with 10% goat serum at room temperature for 20 min and treated with rabbit anti-human EMPI polyclonal antibody (1:100; Abcam, Cambridge, UK) overnight at 4°C. After rinsing, sections were treated with biotin-conjugated antibodies (4A Biotech Co., Ltd., Beijing, China) for 20 min, and biotin-immune complexes were identified with a diaminobenzidine (DAB) substrate immunohistochemistry kit (4A Biotech Co., Ltd.) and hematoxylin stain. Sections were mounted and dehydrated with the cover-slip sealed. For the negative control, sections were treated identically except primary antibody was replaced with PBS. Two pathologists blinded to patient and tissue status assessed the results. Three slides for each specimen were counted, with five fields of view randomly selected for evaluation per section. EMPI expression level was based on the percentage of positive cells and staining intensity. The percentage of positive cells was divided into four levels: 0 points, ≤5% of positive cells; 1 point, 5-25%; 2 points, 25-50%; and 3 points, >50%. The intensity of staining was classified as: 0 points, no staining; 1 point, weak staining (light yellow); 2 points, moderate staining (yellowish-brown); and 3 points, strong staining (brown). The final score of EMPI expression was the product of the EMPI expression rate (percentage score) and intensity: - for 0 points, + to +++ for positive (+ for 1-3 points, ++ for 4-6 points and +++ for 7-9 points).

Quantitative real-time (q) reverse transcription (RT)-PCR. Total RNA was extracted from SGC-7901 cells using TRIzol reagent (Invitrogen) according to the manufacturer’s protocol (12). Total RNA (500 ng) was reverse transcribed using Takara Reverse Transcriptase Reagents (Takara, Shiga, Japan). qRT-PCR was performed with an ABI PRISM 7300 (Applied Biosystems, Inc., Carlsbad, CA, USA) according to the standard protocol for SYBR-Premix ExTaQ (Perfect Real-Time; Takara). Primers for EMPI and β-actin for normalization were as follows: EMPI sense 5'-CCCTCTGGTCTTCTGTGT, anti-sense 5'-ATAGCCGTTGTGATA; β-actin sense 5'-ATCGTCCCCAGAATGCTTCTA, antisense 5'-AGCCCATGCCATCTCATTTGCT. Thermal cycling conditions were 95°C for 1 min, 95°C for 15 sec and 40 cycles at 60°C for 1 min. The relative expression was calculated using the 2-ΔΔCT method in SDS 1.3 software (Applied Biosystems, Inc.).

Western blot analysis. Western blot was performed as previously described (13). Samples were lysed in lysis buffer containing 1% NP-40, 0.1% SDS, 25 mmol/l HEPES, 134 mmol/l NaCl, 1 mmol/l vanadate, 100 mmol/l NaF and 0.5% Na-deoxycholate. After centrifugation at 12000 r/min for 20 min at 4°C, the supernatant was stored at -20°C. Protein concentration was detected with the BCA Protein Assay kit (Tiangen Biotech Co., Ltd., Beijing, China). Protein (50 mg) was resolved on a 10% SDS-PAGE and transferred to nitrocellulose membrane. For EMPI, blots were blocked for 2 h with 5% skim milk and incubated overnight at 4°C with rabbit anti-human EMPI (1:1000), caspase-9 (1:1000; Abcam) and VEGFC (1:1000; Abcam). For β-actin, blots were blocked in 5% non-fat dry milk for 1 h at room temperature and incubated overnight in mouse anti-β-actin (Sigma, St. Louis, MO, USA) overnight at 4°C. After washing, membranes were either incubated with goat anti-mouse fluorescent secondary antibody (1:2000; IRDye800, LI-COR Bioscience, Inc., Lincoln, NE, USA) or DyLight Fluor conjugated goat anti-rabbit secondary antibody (LI-COR Bioscience, Inc.) in the dark for 1 h at room temperature. The blots were scanned and analyzed using the Odyssey Infrared Imaging System (LI-COR Bioscience, Inc.). Western blot data were quantified by normalizing the signal intensity of each sample to that of β-actin (13).

MTT assay. Cell viability was determined using the tetrazolium salt MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide] assay, as previously described (14). Briefly, cells were plated into 96-well culture plates at an optimal density of
5x10^3 cells/ml in 200 µl of culture medium/well. After 24-96 h of culture, 20 µl of 5 mg/ml MTT was added to each well and incubated at 37˚C for 4 h. The medium was then gently aspirated and 150 µl of dimethyl sulfoxide (DMSO) was added to each well to solubilize the formazan crystals. The optical density of each sample was immediately measured using a microplate reader (Bio-Rad, Hercules, CA, USA) at 570 nm.

**Flow cytometry assay.** An Annexin V-FITC-flow cytometry assay (4A Biotech Co., Ltd.) was used to detect the apoptosis rate in the cells after EMP1 transfection, as previously described (15). Cells were seeded into 60-mm dishes for 48 h and grown to 70-75% confluence. After quick detachment from the plate, cells were collected, washed with ice-cold PBS, and resuspended at a cell density of 1x10^6/ml in a binding buffer from the Annexin V-FITC apoptosis detection kit (4A Biotech Co., Ltd.). Cells were then stained with 5 µl of Annexin V-FITC and 10 µl of propidium iodide (PI, 20 µg/ml). The cells were incubated in the dark at 25˚C for 15 min before 10,000 cells were analyzed by a FACSCan flow cytometer (BD Immunocytometry Systems, San Jose, CA, USA) and Cellquest software (BD Immunocytometry Systems) for apoptosis rate determination.

**Invasion and migration assays.** Invasion and migration assays were performed as previously described (16). For the invasion assay, Costar Transwell 8 µm inserts were coated with 50 µg reduced serum Matrigel (BD Biosciences, Bedford, MA, USA). Invasion Chambers (BD China, Shanghai, China) were coated with Matrigel and 7x10^3 cells were added per chamber. Medium supplemented with 10% FBS was used in the lower chamber. For migration assays, the same procedure was used excluding the Matrigel. After 12 h, non-invading cells and media were removed, and cells on the lower surface of the membrane were fixed with polyoxymethylene (Sigma) and stained with 0.1% crystal violet (Sigma) for 0.5 h. Stained cells were counted under a microscope in four randomly selected fields, and the average was used to indicate cell migration and invasion.

**Statistical analysis.** All statistical analyses were performed using SPSS 16.0 software (IBM, Chicago, IL, USA), as previously described (17). For the clinicopathological features, P-values were calculated using the χ^2 test. Student's t-test was used to analyze the difference between groups. Survival distributions were estimated with the Kaplan-Meier method and compared with the log-rank test. A P-value <0.05 was considered to be statistically significant.

**Results**

**EMP1 protein expression in gastric cancer and normal tissues.** EMP1 staining in gastric cancer tissue was negative or weak relative to normal adjacent gastric tissues that exhibited light yellow to brown staining. EMP1 expression was significantly lower (P<0.05) in gastric cancer tissue (expressed in 41.5%, 27/65) than normal tissue (expressed in 70.4%, 19/27) (Table I, Fig. 1). Western blot analysis showed that the expression of EMP1
in cancer lesions was significantly less than adjacent normal tissue (0.153±0.012 and 0.626±0.058, respectively; P<0.05) (Fig. 2). The expression of EMP1 negatively correlated with tumor invasion, lymph node metastasis, clinical stages and pathological differentiation (P<0.05, Table II).

**EMP1 expression and prognosis.** Patients were followed up for 60 months for survival analysis. At the end of the study in 2013, 37 of 63 patients had survived. Patients were divided into two groups according to expression level of EMP1. Of the 27 patients with positive levels of EMP1 expression, 19 were still alive, yielding a survival rate of 70.3%. Of the 38 patients with undetectable levels of EMP1 expression, only 18 were still alive, yielding a survival rate of 47.4%. Patients with high levels of EMP1 had a significantly higher 5-year survival rate than those with low levels of EMP1 (P<0.05) (Fig. 3).

**Stable transfection of EMP1 cDNA in gastric cancer cells.** SGC-7901 cells stably transfected with EMP1 overexpressed EMP1 (named as LeEMP1 cells). Control SGC-7901 cells were transfected with an empty vector (named as LeEmpty cells). The expression of EMP1 mRNA and protein was significantly elevated in LeEMP1 cells relative to control cells (P<0.05).

EMPI mRNA levels detected by RT-PCR was significantly higher in LeEMP1 cells (0.626±0.058) than LeEmpty cells (0.188±0.018) (P<0.05; Fig. 4A). Western blot analysis found that the level of immunoreactive protein was significantly higher in EMP1 transfected cells (0.731±0.070) relative to controls cells (0.244±0.019) (P<0.05; Fig. 4B).

**Effects of EMP1 overexpression on gastric cancer cells.** Next, we assessed the effect of EMP1 expression on the regulation of gastric cancer cell viability. MTT assay showed that relative proliferative capacity of LeEMP1 cells grew significantly slower at 24, 48, 72 and 96 h relative to LeEmpty cells (P<0.05;
Meanwhile, there was a significant increase in the early apoptosis rate in LeEMP1 cells (13.2±1.5%) relative to control cells (2.2±0.5%) (P<0.05; Fig. 6). SGC-7901 cells transfected with EMP1 or empty vector were transferred to transwell chambers or Matrigel-coated transwell chambers to evaluate the effect of EMP1 on cell invasion potential. Overexpression of EMP1 clearly significantly decreased cell migration and invasion of SGC-7901 cells (157.0±16.0 and 112.0±12.0, respectively) relative to control cells (243.0±21.0 and 203.0±19.0, respectively) (P<0.05; Fig. 7).

To further study the mechanisms by which EMP1 inhibited gastric cancer cell proliferation, cell apoptosis, migration and invasion, we analyzed the expression of two proteins with critical roles in these processes, caspase-9 and VEGFC. Western blot analysis revealed that overexpression of EMP1 in SGC-7901 cells significantly upregulated caspase-9 protein expression (0.501±0.050) relative to control cells (0.114±0.010) (P<0.05; Fig. 8). In contrast, the level of VEGFC protein expression was significantly lower in SGC-7901 cells overexpressing EMP1 (0.135±0.011) than control cells (0.619±0.074) (P<0.05; Fig. 8).

Discussion

Several studies have shown that the EMP1 gene is expressed in a number of normal tissues (7,18-23). In this study, we localized and quantified for the first time EMP1 protein expression in gastric cancer tissue and normal gastric tissue using immunohistochemistry and immunoblotting. EMP1 protein levels were significantly lower in gastric carcinoma than in normal tissue and EMP1 protein levels correlated with tumor invasion, lymph node metastasis and clinical stage of gastric cancer. Since dedifferentiation is a hallmark of tumor cells, our findings suggest that a decline in EMP1 level is a factor in the development and progression of gastric cancer. In a study evaluating several types of human breast cancer cells with different metastatic characteristics, EMP1 gene expression was correlated with cell invasion and other properties of metastasis (24). EMP1 gene expression was downregulated in oral squamous cell carcinoma and this downregulation was correlated with lymph node metastasis (25). Therefore, the EMP1 gene may be an important factor for the regulation of cell signaling, cell communication and adhesion (26).

Currently an effective treatment paradigm for gastric cancer is surgical extended lesion resection, accompanied by chemotherapy and/or radiotherapy before and after surgery. However, the survival rate with this strategy is not very satisfactory (27,28). Therefore, efforts should be directed toward early detection of gastric cancer and the refinement of individual-based treatment strategies. Conventional treatment and prognosis of gastric cancer rely mainly on TNM classification (29). This system is subjective and not informative for early gastric cancer, and offers limited information on the disease severity, prognosis and response to treatment. Early detection of gastric cancer is the most effective way to improve survival (30). Using survival analysis, we found that EMP1 expression-
Figure 6. Effects of EMP1 overexpression on cell apoptosis. (A) Cells were stained with 5 µl Annexin V-FITC and 10 µl PI (20 µg/ml). Samples were acquired on a FACScan flow cytometer and 10,000 cells analyzed with Cellquest software; (B) Gastric cancer cells overexpressing EMP1 (LeEMP1) exhibit significantly more apoptosis than empty vector transfected cells (LeEmpty). *P<0.05.

Figure 7. Effects of EMP1 overexpression on cell migration and invasion. (A) Histological sections of cell migration and invasion in LeEmpty and LeEMP1 cells; (B) The number of migrating cells is significantly greater in LeEmpty cells than LeEMP1 cells; (C) Number of invading cells is greater in LeEmpty than LeEMP1 transfected cells. *P<0.05.
positive patients had a significantly higher 5-year overall survival rate than patients with undetectable EMP1 expression. Thus, combining information from the TNM classification system and EMP1 expression scores may provide valuable information for clinicians regarding prognosis, prediction of disease severity and selection of treatment regimens.

Furthermore, in vitro experiments demonstrated for the first time that gastric cancer cells with high EMP1 expression had significantly weakened proliferation, significantly increased apoptosis, markedly increased caspase-9 and reduced VEGFC protein levels. Previously, overexpression of EMP1 in an esophageal cancer cell line slowed esophageal cancer cell growth and yielded fewer S-phase cells and more G1-phase cells (26). Together with our findings, these data suggest that low levels of EMP1 affect cellular processes that are abnormally regulated in cancer. Mitochondria are not only the site of cellular respiration and oxidative phosphorylation, but also the regulation center of apoptosis. Cytochrome C released from mitochondria to the cytoplasm associates with apoptotic protease activating factor (Apaf-1) to form a multiservice complex in the presence of deoxyribonucleotide triphosphate (dNTP) (31). This complex interacts with pro-caspase-9 to form an apoptosome and, following dimerization, results in autoactivation of caspase-9. This activated caspase-9 stimulates other caspases, such as caspase-3 and caspase-7, culminating in apoptosis via signaling cascades (32-34). We found in this study that high expression of EMP1 is associated with significantly higher expression of caspase-9 protein, implicating a mitochondrial apoptosis pathway in EMP1-induced apoptosis.

VEGF is a member of the platelet-derived growth factor (PDGF) family and is the most important vascular endothelial growth-stimulating factor during tumor angiogenesis. VEGFC is a recently identified member of the VEGF family, which promotes the proliferation of endothelial cells, increases vascular permeability, and functions as a key factor in tumor angiogenesis, invasion and metastasis (35,36). We found in this study that overexpression of EMP1 is associated with a significant decrease in VEGFC expression. This finding suggests that EMP1 may inhibit tumor angiogenesis by suppressing VEGFC expression and hence tumor metastasis.

In summary, we demonstrated that EMP1 protein levels were significantly reduced in gastric carcinoma and were associated with tumor invasion, lymph node metastasis, clinical stage and cell differentiation. EMP1 is involved in a number of biological processes including proliferation, apoptosis, invasion and metastasis of gastric cancer. Given the complexity of carcinogenesis, further research is needed to understand the molecular mechanism underlying EMP1 regulation of this process. Our findings identify a novel potential therapeutic target for gastric cancer and suggest EMP1 may be a reliable biomarker for prognosis of gastric cancer.
