Abstract. $^{18}$F-fluorodeoxyglucose positron-emission tomography/computed tomography ($^{18}$F-FDG-PET/CT) is important in lung cancer diagnosis; false negatives are often caused by ground-glass nodules (GGNs). PET/CT utility in GGN diagnosis is unknown. The associations between GGN CT findings (size, properties), the pathological diagnosis and maximum standardized uptake value ($\text{SUV}_{\text{max}}$) were explored. Sixty-six patients with pathological stage IA1-IIA lung adenocarcinoma underwent surgical resection and PET/CT between January 2010 and December 2014. Clinical characteristics, CT findings, pathological diagnoses and PET/CT findings were retrospectively examined. The age range was 47-86 years (median, 69 years), the female/male ratio was 38:28 and the pathological stage was IA1, IA2, IA3, IB and IIA in 5, 30, 21, 9 and 1, respectively. Total and solid-part lesion diameters ranged from 7.00-41.13 mm (median, 19.43 mm) and 0.00-23.23 mm (median, 4.55 mm), respectively; the solid-part ratio (solid-part diameter/total diameter) was 0-77% (median, 20%). $\text{SUV}_{\text{max}}$ ranged from a value too low for evaluation to 3.9 (median, 1.0). Pathological diagnoses were adenocarcinoma in situ (AIS), minimally invasive adenocarcinoma (MIA), lepidic-predominant adenocarcinoma (LPA) and papillary-predominant adenocarcinoma (PPA) in 17, 15, 32 and 2, respectively. Correlation coefficients for each factor and $\text{SUV}_{\text{max}}$ for total and solid-part diameters were 0.513 ($p<0.0001$) and 0.461 ($p<0.0001$), respectively. All pure GGNs showed clinically unimportant $\text{SUV}_{\text{max}}<2.5$, even though some large GGNs were included (maximum, 40.0 mm). A total diameter ≥20 mm was significantly associated with FDG uptake ($p<0.0001$). $\text{SUV}_{\text{max}}$ were <2.5 when the solid-part diameter was <4.55 mm. The AIS-MIA group showed significantly lower $\text{SUV}_{\text{max}}$ than the LPA-PPA group ($p=0.0008$). There was no clinically important $\text{SUV}_{\text{max}}$ with diagnostic value for pure or small part-solid GGNs. There were medium correlations for GGN total diameter, solid-part diameter, and $\text{SUV}_{\text{max}}$. We should note PET/CT’s limitations in GGN diagnosis.

Introduction

$^{18}$F-fluorodeoxyglucose positron emission tomography/computed tomography ($^{18}$F-FDG-PET/CT) is widely used to make qualitative diagnoses. When treating lung cancers, for example, it is used to determine the malignancy of lesions in the lungs and lymph nodes. However, PET images generally have poorer resolution than CT images and scans of lung tissue are particularly affected by respiratory rhythms. These factors are considered to limit PET's usefulness in diagnosing small-diameter lesions such as ground-glass nodules (GGNs (1-3). However, few publications have examined PET/CT’s utility when examining GGNs alone (4,5). Moreover, it has not been established definitively whether this imaging modality is useful for certain kinds of GGNs and how such data should be evaluated. Well-differentiated adenocarcinomas are among the types of GGN lesions identifiable on CT. However, their small diameter makes it difficult to collect pathological specimens in many cases (for example, by means of bronchoscopy or CT-guided needle lung biopsy). This raises an important question regarding the utility of PET/CT for determining the benignity or malignancy of GGNs. In this study, we examined PET/CT’s clinical utility for the diagnosis of GGN lesions by comparing preoperative CT and PET/CT findings of patients who underwent surgery at Japanese Red Cross Okayama Hospital and who were diagnosed with lung cancer based on histological findings.

Patients and methods

Records of patients diagnosed with lung cancer following pulmonary resection at Japanese Red Cross Okayama Hospital between January 2010 and December 2014 were reviewed retrospectively. Only patients who underwent PET/CT and whose preoperative CT findings indicated GGNs were analyzed.

All patients were imaged using an Aquilion 64 CT scanner at Japanese Red Cross Okayama Hospital (Toshiba Medical Systems, Otawara, Japan). The scan settings were as follows: slice dimensions = 512x512 pixels, slice thickness = 1.0 mm, scanning interval = 0.8 mm, tube voltage =120 mA (with automatic tube voltage modulation), and pitch factor = 0.844. GGNs were evaluated on horizontal chest CT images in terms of total diameter (the long axis of the lesion), solid-part diameter (the long axis of the hyperechoic, low-contrast part, as determined visually), and solid-part ratio (the solid-part diameter/total diameter) (Fig. 1). If multiple GGNs were observed simultaneously in a slice, only the lesion with the largest total diameter was analyzed.

PET/CT scanning was performed at Okayama Diagnostic Imaging Center and Okayama Kyokuto Hospital. At the former, patients were scanned using a lutetium oxyorthosilicate (LSO)-based Biograph Sensation 16 PET/CT scanner with manufacturer-recommended settings (Siemens, Munchen, Germany), FDG (3.7 MBq/kg) was administered intravenously after the patient had fasted for ≥5 h; scanning began 90 min thereafter. At the latter, patients were scanned using a Discovery LS PET/CT system with manufacturer-recommended settings (General Electric Company, Boston, MA, USA). FDG (6 MBq/kg) was administered intravenously after the patient had fasted for ≥4 h; scanning began 50 and 120 min thereafter for early- and delayed-phase images, respectively. Only early-phase images were used in the analysis. Both facilities conduct daily inspections for PET/CT quality control. Various studies have been published on the evaluation of PET findings. This study employed the maximum standardized uptake value (SUV$_{\text{max}}$), a commonly used metric in Japan at present. Pulmonary nodules were judged to have clinically important FDG uptake when the SUV$_{\text{max}}$ was ≥2.5 (2,6).

The statistical analysis was performed using EZR software version 1.36 (Saitama Medical Center, Jichi Medical University, Saitama, Japan) (7). In the statistical analysis, an SUV$_{\text{max}}$ too low to evaluate was treated as SUV$_{\text{max}}$=0.0. p≤0.05 was considered to indicate a statistically significant difference in two-group comparisons. Correlations were evaluated using the Pearson product-moment correlation coefficient; r≥0.4 was considered to indicate a moderate correlation. Fischer's exact test was used to analyze frequency distributions. The t-test was used to determine whether differences in the means of two sets of samples were significant.

All lung cancer diagnoses were corroborated by the pathological histology of the biopsied specimens. Original histology-based diagnoses were based on the General Rules for the Clinical and Pathological Classification of Lung Cancer of the Japan Lung Cancer Society (8th edition) and the TNM staging system of the International Association for the Study of Lung Cancer (8th edition) (8). The same tissue specimens were re-examined and classified in the present study using the World Health Organization Classification of Tumors of the Lung, Pleura, Thymus, and Heart (4th edition) (9).

Patients’ clinical characteristics, CT findings (total diameter, solid-part diameter, and solid-part ratio), pathological diagnosis, and their relationships with the SUV$_{\text{max}}$ were analyzed statistically. This study was conducted with the approval of the Ethics Committee of Japanese Red Cross Okayama Hospital.

Results

In total, 66 patients who were diagnosed with lung cancer following pulmonary resection at Japanese Red Cross Okayama Hospital between January 2010 and December 2014 were analyzed. All had undergone PET/CT and had preoperative CT findings indicating GGNs. The subjects ranged in age from 47-86 years (median, 69 years) and consisted of 28 men and 38 women. All were diagnosed with lung adenocarcinoma; MIA, minimally invasive adenocarcinoma; LPA, lepidic predominant adenocarcinoma; PPA, papillary predominant adenocarcinoma.
the solid-part ratios ranged from 0-77% (median, 20%). A total of 22 lesions were diagnosed as pure GGNs. The SUV\(_{\text{max}}\) ranged from a value too low to be evaluated to a maximum of 3.9 (median, 1.0). The SUV\(_{\text{max}}\) ranged from 1.00-1.49 in 34 patients (51.5%), 1.50-1.99 in 19 (28.8%), 2.00-2.49 in 11, (16.7%), and ≥2.5 in 6 (9.1%). The histopathological classifications of the adenocarcinoma subtype were adenocarcinoma in situ (AIS) in 17 patients, minimally invasive adenocarcinoma (MIA) in 15, lepidic-predominant adenocarcinoma (LPA) in 32, and papillary-predominant adenocarcinoma (PPA) in 2 (10) (Table I). The SUV\(_{\text{max}}\) correlated with each CT metric as follows: \(r=0.513\) for the total diameter (\(p<0.0001\)), \(r=0.461\) for the solid-part diameter, and \(r=0.307\) for the solid-part ratio (\(p<0.0001\)). Patients with total GGN diameters ≥20 mm were significantly more likely to have an SUV\(_{\text{max}}\) ≥2.5 than were patients with smaller lesions (\(p<0.0001\)). No pure GGN or lesion with a solid-part diameter <4.55 mm exhibited an SUV\(_{\text{max}}\) ≥2.5. Eight tumors with an SUV\(_{\text{max}}\) <2.5 were classified as pure GGNs (AIS, 3; MIA, 4; and LPA, 2). There was no significant difference in the frequency of SUV\(_{\text{max}}\) ≥2.5 in the AIS-MIA group and the LPA-PPA group (\(p=0.198\)) (Table II). All had an SUV\(_{\text{max}}\) ≥1.0 and comprised 38.1% of all pure GGNs observed. The AIS-MIA group showed a significantly lower SUV\(_{\text{max}}\) than the LPA-PPA group (\(p=0.0008\)). The average value of SUV\(_{\text{max}}\) in each group was 0.61 (95% confidence interval 0.309-0.919) in the AIS-MIA group and 1.43 (95% confidence interval 1.07-1.789) in the LPA-PPA group (Fig. 2).

Discussion

Our investigation observed a moderate correlation between the major-axis diameter and SUV\(_{\text{max}}\) of GGNs. The potential of using the SUV\(_{\text{max}}\) as a reference value was demonstrated by the fact that it was better correlated with the solid-part diameter than the total diameter. However, it is important to note that the correlation was low for pure GGNs and small-diameter lesions. Moreover, in some cases, imaging findings diverged from pathological findings; for example, one case was classified as AIS by postoperative histopathology despite the lesion having a solid part that had been observed before surgery. We did not use high-resolution CT (HR-CT) scanners, but the resolution of our CT images was typical for clinical scanning procedures. Nonetheless, perhaps this divergence would have been less had our scans been performed with greater precision using such equipment.

In this study, we also examined the relationship between AIS, MIA, LPA, PPA and SUV\(_{\text{max}}\). There was a significant difference in the mean value of SUV\(_{\text{max}}\) in the AIS-MIA group and the LPA-PPA group, but the clear cut-off value is still unknown. Although the possibility of SUV\(_{\text{max}}\) 1.0 being a point dividing the two groups was shown in this study, and care should be taken for GGNs with SUV\(_{\text{max}}\) higher than that, further investigation is necessary in the future.

Normal lung tissue has an SUV of 0.6 (range, 0.2-1.8) and many past studies have used the criterion of an SUV\(_{\text{max}}\) ≥2.5 to diagnose a finding as malignant when performing PET/CT examinations of pulmonary nodules (11). Since we did not analyze noncancerous lesions in this study, the sensitivity in detecting cancer of SUV\(_{\text{max}}\) ≥2.5 is unknown. However, in this study, even in the LAP-PPA group, the mean value of SUV\(_{\text{max}}\) is <2.5; thus, at least for GGN lesions, it is not an indicator for a non-carcinoma. The SUV is a semi-quantitative value that is affected by factors such as body type, blood sugar levels, and scanning time, and can further vary between different devices or image reconstruction software packages. Because of its simplicity and intuitiveness, it is widely used in clinical procedures to complement visual assessments such as the maximum intensity projection. Even though we analyzed PET/CT scans that were performed at two hospitals, we decided that since the SUV\(_{\text{max}}\) was measured at both locations, it could be used as a major assessment measure with a certain level of objectivity. However, we cannot deny the possibility that using scanning data from multiple institutions could have influenced our assessment. The SUV tends to be low in cells with low glucose metabolism on PET images, for example, highly differentiated lung adenocarcinomas and hepatocellular, renal, prostate, and gastric cancers. Past investigations have found that pure GGNs exhibit median SUV values of around 1.0 (4,12); our SUV\(_{\text{max}}\) data were not greatly divergent from these values. In addition, PET has low spatial resolution (7-8 mm), making it difficult to assess nodules less than 10 mm in diameter, generally speaking (2,13,14). Moreover, one study found that the SUV\(_{\text{max}}\) of lung carcinomas showing localized ground-glass opacities

*There was no significant difference in the frequency of SUV\(_{\text{max}}\) ≥2.5 in the AIS-MIA group and the LPA-PPA group (\(p=0.198\)). AAH, atypical adenomatous hyperplasia; AIS, adenocarcinoma in situ; MIA, minimally invasive adenocarcinoma; LPA, lepidic predominant adenocarcinoma; PPA, papillary predominant adenocarcinoma.
was not significantly different from the \( \text{SUV}_{\text{max}} \) observed from inflammatory lesions (5). Therefore, we advise caution when using the \( \text{SUV}_{\text{max}} \) to determine the benignity or malignancy of lung cancers.

PET/CT-based research is becoming more diverse and is utilized in conjunction with a variety of different objectives and use cases. For example, one recent study found that the preoperative \( \text{SUV}_{\text{max}} \) could serve as a prognostic factor in c-stage IA lung adenocarcinomas (15). Technological advances are helping to increase the diagnostic accuracy of PET/CT; recent efforts have focused on developing image reconstruction techniques, improving spatial resolution by means of time-of-flight methods, and reducing partial-volume effects (16,17). While the clinical value of PET/CT in evaluating GGNs is still limited at present, it could increase in the future, and thus its evolution must be monitored carefully going forward.

This study is novel in that \( \text{SUV}_{\text{max}} \) was analyzed based on currently used pathological classifications of lung adenocarcinoma, suggesting the possibility of \( \text{SUV}_{\text{max}} \) value in lesions with higher malignancy, even in GGN lesions. In order to scientifically confirm the relationship between pathological findings and \( \text{SUV}_{\text{max}} \) values, future larger-scale prospective observational research with a focus on similar imaging conditions is necessary.

This study was presented at the 2015 World Conference on Lung Cancer (Denver, CO, USA).
