Abstract. Non-alcoholic fatty liver disease (NAFLD) comprises a range of liver diseases, between steatosis and non-alcoholic steatohepatitis and liver cirrhosis, which are closely associated with diabetes mellitus. Previous studies have indicated that oxidative stress is a key factor in the development of NAFLD. Molecular hydrogen (H2) may ameliorate oxidative stress injuries by selectively neutralizing peroxynitrite and hydroxyl radicals. The present study evaluated the effects of H2 on NAFLD in rats and concluded that H2-rich saline had significant therapeutic effects on NAFLD induced by hyperglycemia and hyperlipidemia, as demonstrated by hematoxylin and eosin and terminal deoxynucleotidyl-transferase-mediated dUTP nick end labeling staining. H2-rich saline improved fasting blood glucose, fasting insulin, insulin sensitivity and glucose tolerance, and lowered the expression levels of tumor necrosis factor alpha, interleukin-1 beta, 3-nitrotyrosine and 8-hydroxy-2′-deoxyguanosine in the liver. In addition, the present study revealed that H2-rich saline could significantly increase peroxisome proliferator-activated receptor (PPAR) α and PPARγ expression in hepatocytes. In conclusion, H2-rich saline may significantly improve NAFLD, possibly by reducing oxidative stress and activating hepatic PPARα and PPARγ expression.

Introduction

Non-alcoholic fatty liver disease (NAFLD) represents a range of liver diseases, between steatosis and non-alcoholic steatohepatitis and liver cirrhosis (1), and is considered a public health problem (2). Evidence suggests that NAFLD is more common in patients with diabetes compared with the general population by approximately threefold (3). Prospective studies have revealed that diabetes mellitus (DM) is an independent risk factor for NAFLD development and liver-associated mortality (4, 5).

A number of mechanisms are shared between NAFLD and DM, including insulin resistance, hyperinsulinemia, and increased oxidative stress and inflammation. Among them, oxidative stress and inflammation serve an important role (6). In DM with insulin resistance, increased lipolysis occurs, generating more free fatty acids (FFAs). FFAs may be oxidized in the mitochondria, and increased FFA oxidation leads to the generation of more reactive oxygen species (ROS), which can trigger oxidative stress injuries. Therefore, the study and development of novel antioxidant drugs to neutralize free radicals and to reduce their biomolecular effects may provide potential options for the prevention and treatment of NAFLD.

Molecular hydrogen (H2) is a colorless, odorless and tasteless diatomic gas. It has previously been reported that H2 could ameliorate oxidative stress injuries by selectively scavenging peroxynitrite (ONOO−) and hydroxyl radicals (·OH), the two most cytotoxic ROS (7). The therapeutic effects of H2 have been demonstrated in ischemia-reperfusion injuries (8, 9), transplantation injuries (10) and other injuries associated with oxidative stress. H2-rich saline has been widely studied in atherosclerosis, stress-induced nerve damage, type 2 DM (T2DM), cisplatin-induced renal damage, type 2 DM (T2DM), cisplatin-induced renal injury and Parkinson’s disease (11-14).

In 2011, Kamimura et al (15) reported that H2 was beneficial for obesity, DM and energy metabolism in mice. Considering the roles of oxidative stress in NAFLD injury, the present study hypothesized that, as a specific free radical scavenger, H2 could improve NAFLD induced by a high-sugar and high-fat diet, and evaluated the effects of H2 on NAFLD as well as the possible underlying mechanisms.
Materials and methods

Ethics statement. All animal experimental protocols were approved by the ethics committee of Changhai Hospital affiliated to the Second Military Medical University (Shanghai, China) and were conducted in accordance with their guidelines.

Animals and grouping. A total of 24 male Sprague-Dawley rats (age, 10 weeks; weight, 250-280 g) were purchased from the Shanghai Laboratory Animal Center of the Chinese Academy of Sciences (Shanghai, China). Rats were housed at 24±2°C under a 12-h light/dark cycle, and fed ad libitum. All rats received humane care according to the Guide for the Care and Use of Laboratory Animals (16). The animals were randomly divided into three groups: i) The control group (n=8), which was fed a normal diet (15% kcal from fat), and normal saline (5 ml/kg) was administered intraperitoneally twice daily; ii) the model group (n=8), which was fed a high-sugar and high-fat diet, and normal saline (5 ml/kg) was administered intraperitoneally twice daily; and iii) the H2-rich saline treatment group (n=8), which was fed a high-sugar and high-fat diet, and H2-rich saline (5 ml/kg) was administered intraperitoneally twice daily. The high-fat diet was prepared according to Li et al (17) and contained 2% cholesterol, 7% lard, 8.3% yolk, 16.7% sucrose and 66% standard diet, which provided 4.66 kcal/g with an energy composition of 31.59% from fat, 51.73% from carbohydrate and 16.68% from protein.

Animal model establishment. Lipotoxicity was induced by a high-fat diet, and streptozotocin (STZ; Sigma-Aldrich; Merck Millipore, Darmstadt, Germany) was injected to cause glucose toxicity, which subsequently led to islet β-cell failure and apoptosis (18). Briefly, a single injection of STZ (25 mg/kg) was administered via the tail vein in 0.1 mol/l citrate buffer (pH 4.2) followed by a continuous high-fat and high-sugar diet for 8 weeks. Subsequently, an oral glucose tolerance test was performed as described previously (19). Rats from the control and treated groups received 2 g/kg glucose orally; a 2 h blood glucose result measuring >1.2 mmol/l or a random blood glucose result measuring >16.8 mmol/l in rats was considered successful model establishment.

H2-rich saline preparation. H2-rich saline was prepared as previously described (16). Briefly, H2 gas was dissolved in normal saline for 2 h under 0.4 MPa pressure to saturation. The concentration was measured with gas chromatography to ensure the hydrogen level was >0.6 mmol. H2-rich saline was prepared each week and stored at 4°C in aluminum bags until ready for use.

Determination of serum biochemical markers, and insulin sensitivity and resistance. Blood was collected from the tail vein at 8 weeks, and serum alanine transferase (ALT), total bilirubin (TBIL), total cholesterol (TC), triglycerides (TG), fasting blood glucose (FBG) and fasting insulin (FINs) levels were determined using a biochemical analyzer. In addition, the insulin sensitivity index (ISI) and homeostasis model assessment-insulin resistance (HOMA-IR) were calculated as follows: HOMA-IR = (fasting blood glucose x fasting insulin) / 22.5; ISI = 1/(fasting blood glucose x fasting insulin). Insulin tolerance tests were conducted on the three rat groups as described previously (20).

Hematoxylin and eosin (H&E) staining. After 8 weeks, the rats were anesthetized using an intraperitoneal injection of 10% aqueous solution (0.3 ml/100 g) of chloral hydrate (Huai’an Xingzhi Biological Technology Co., Ltd., Huaiian, China) and their livers were harvested, sectioned, fixed in 4% paraformaldehyde and embedded in paraffin. The paraffin blocks were then sliced into 4 µm sections and deparaffinized according to Shi et al (21).

Sections were stained with H&E and images were captured using a light microscope. A pathologist that was blinded to the animal groups evaluated the slides and scored each liver tissue specimen for steatosis, inflammation and fibrosis based on the criteria proposed by previous studies (22-24). Briefly, for steatosis: Score 0, none present; score 1, steatosis <33% of the parenchyma; score 2, steatosis 34-66% of the parenchyma; score 3, steatosis >67% of the parenchyma. For inflammation: Score 0, no foci of inflammation; score 1, <1 foci per two 200x fields; score 2, one foci per two 200x fields; score 3, one to two foci per one 200x field; score 4, >2 foci per one 200x field. For fibrosis: Score 1, zone-3 perisinusoidal fibrosis; score 2, zone-3 perisinusoidal fibrosis with portal fibrosis; score 3, zone-3 perisinusoidal fibrosis and portal fibrosis with bridging fibrosis; and score 4, cirrhosis. The total score (steatosis + inflammation + fibrosis) of each rat was calculated and the average score for each group was determined.

Terminal deoxynucleotidyl-transferase-mediated dUTP nick end labeling (TUNEL) staining. TUNEL staining was performed using an In Situ Cell Death Detection kit (Roche Diagnostics, Basel, Switzerland). Liver sections were heated to 60°C for dewaxing and were then rehydrated according to standard protocols and as previously reported (21). After cooling to room temperature, the sections were incubated with 20 µg/ml protease K solution for 20 min followed by incubation in TUNEL reaction mixture for 1 h at 37°C. Converter-alkaline phosphatase antibody was then added to the samples for 1 h at 37°C. Subsequently, sections were washed with PBS three times for 5 min, followed by color development in the dark with nitroblue tetrazolium and 5-bromo-4-chloro-3-indolylphosphate. Ten fields were randomly chosen (x200). The number of apoptotic hepatocytes was counted in each field and an average was calculated.

Determination of tumor necrosis factor alpha (TNF-α) and interleukin-1 beta (IL-1β). Rat livers were collected and washed in normal saline, and were then homogenized immediately on ice in 1 ml normal saline at 2-8°C. The homogenates were centrifuged at 3,000 x g at 4°C for 15 min. The expression levels of TNF-α (catalog no. H052) and IL-1β (catalog no. H002) were measured using commercial ELISA kits (Nanjing Jianchen Bioengineering Institute, Nanjing, China) according to the manufacturer’s protocol.

Determination of caspase-3 (CASP-3) activity. Similar methods were used to determine CASP-3 activity as previously described (21). Livers were harvested at 8 weeks, and...
CASP-3 activity was determined with the CASP-3/PP32 Fluorometric Assay kit (BioVision, Inc., Milpitas, CA, USA). Briefly, hepatocyte lysates were incubated with 10 μg/ml proteinase K for 30 min at 37°C in a 96-well plate. The peptide substrate DEVD-APC (5 μl) was then added to initiate the reaction. After incubation in the dark at 37°C, a fluorometer was used to read the plate using a 400-nm excitation filter and a 505-nm emission filter. Fold increase in CASP-3 activity was calculated by comparing with the level of the control.

**Determination of 3-nitrotyrosine (3-NT) and 8-hydroxy-2′-deoxyguanine (8-OHdG).** Similar methods were employed as previously reported (25). Liver sections were deparaffinized in xylene, rehydrated with ethanol and pretreated with 10 μg/ml proteinase K for 30 min at 37°C. Subsequently, the sections were incubated in 10% bovine serum albumin (Nanjing Jianchen Bioengineering Institute) for 20 min. After overnight incubation at room temperature with anti-8-OHdG (1:200; catalog no. ZY-1131R) and anti-3-NT antibodies (1:200; catalog no. 28-60252P) from Heyzer Ye Biological Technology Co., Ltd. (Shanghai, China). An alkaline phosphatase-conjugated secondary antibody (1:500; catalog no. E030210; Shanghai Yanhua Bio-Tech Co., Ltd., Shanghai, China) was added for 1 h at 37°C, and the sections were incubated with diaminobenzidine. The number of 8-OHdG- and 3-NT-positive cells were counted under a light microscope, and integral optical densities were calculated with Image-Pro Plus software version 6 (Media Cybernetics, Inc., Rockville, MD, USA).

The concentrations of 3-NT and 8-OHdG in the liver were determined using commercial ELISA kits [catalog nos. JK-(a)-5053 and JK-(a)-1571; Shanghai Jinkang Medicine Technology Co., Ltd., Shanghai, China], according to the manufacturer’s protocol. Liver tissues were homogenized in 2 ml 10 mM phosphate-buffered saline (pH 7.4). After centrifugation at 10,000 x g for 30 min at 37°C, the levels of 3-NT and 8-OHdG in the supernatant were measured using the corresponding kits.

**Determination of the expression levels of peroxisome proliferator-activated receptor (PPARα) and PPARγ.** The protein expression levels of PPARα and PPARγ in the liver were examined using immunohistochemistry. The transcription of PPARα and PPARγ were determined by reverse transcription-quantitative polymerase chain reaction (RT-qPCR). Total RNA was extracted using TRIzol® reagent according to the manufacturer’s protocol. Liver tissues were homogenized in 2 ml 10 mM phosphate-buffered saline (pH 7.4). After centrifugation at 10,000 x g for 30 min at 37°C, the levels of 3-NT and 8-OHdG in the supernatant were measured using the corresponding kits.

The primer sequences were as follows: PPARα, forward 5′-GGT CTT AAC CGG CCC-3′, reverse 5′-AAA CGC AAC GTA GAG-3′; PPARγ, forward 5′-CTG TTT TAT GCT GTT ATG GGT GAA A-3′, and reverse 5′-GCA CTC TCT GGG TCA A-3′; and GAPDH, forward 5′-TGG GTG TGA ACC ACG AGA A-3′, and reverse 5′-GGC ATG GAC TGT GGG CAT GA-3′. The ΔΔCq method was used to to normalize mRNA expression levels to those of GAPDH (26).

**Statistical analysis.** All data are presented as the mean ± standard deviation (n=8) and were analyzed with SPSS 9.1 software (SPSS, Inc., Chicago, IL, USA). Differences between groups were compared with one-way analysis of variance followed by the Student-Newman-Keuls post hoc test. Glucose tolerance and insulin tolerance test results were analyzed by mixed model for repeatedly measured data for multiple comparisons. P<0.05 was considered to indicate a statistically significant difference.

**Results**

**H&E staining of the liver.** H&E staining was used to observe liver morphology by microscopy (Fig. 1). As presented in Fig. 1A, rats in the control group demonstrated a normal architecture with hepatocytes arranged in plates aligned to sinusoids converging to centrilobular veins. Rats in the model group, which were fed a high-sugar and high-fat diet, presented with moderate to severe steatosis, ballooning degeneration, piecemeal necrosis and inflammatory cell infiltration. In addition, early fibrosis was detected. In the H2 group, a relatively normal histologic architecture was observed, with little steatosis, ballooning degeneration, necrosis and inflammatory cell infiltration. The average histopathological scores are presented in Fig. 1C. Scores in the model group were significantly higher than those in the control and H2 groups (P<0.05 model group vs. control and H2 groups).

**TUNEL staining.** For analysis of apoptosis, TUNEL staining results are presented in Fig. 1B. At a magnification of x200, the nuclei of hepatocytes were clearly stained. Some occasional TUNEL-positive cells were detected in the control group. Significantly more apoptotic cells were present in the model group, in which the apoptotic cells were significantly shrunken and the nuclei were strongly stained. In the H2 group, the number of apoptotic cells was significantly smaller than that in the model group (Fig. 1D; P<0.05 model group vs. control and H2 groups).

**Serum biochemical markers.** To assess lipid metabolism and liver function, serum levels of ALT, TBIL, TC and TG were measured at 8 weeks. ALT and TBIL levels in the model group were slightly higher compared with the control and H2 groups (Fig. 2A and B); however, the differences were not statistically significant (P=0.08). The TC and TG levels in the model group were significantly higher compared with those in the control and H2 groups (Fig. 2C and D; P<0.05 model group vs. control and H2 groups).

At 8 weeks, the serum FBG and FINS levels were also examined to assess the function of pancreas islets (Fig. 2E and F). For FBG, the differences between the model group and the control...
or H₂ groups were not statistically significant; for FINS, the difference was statistically significant (P<0.05 model group vs. control and H₂ groups).

Finally, the ISI and HOMA-IR were calculated to assess insulin resistance, and it was revealed that in the H₂ group, when compared to the model group, the ISI was significantly elevated and the HOMA-IR was significantly reduced (P<0.05 H₂ vs. model group).

Insulin sensitivity and glucose tolerance tests. At 8 weeks, the insulin tolerance test and glucose tolerance test were performed. The insulin tolerance test was performed to assess pituitary function and adrenal function, and as presented in Fig. 2I, following injection of insulin serum glucose levels gradually decreased over time. The rate of decrease in the model group was significantly lower than that in the other two groups. At 60 and 90 min after the injection, the difference was statistically significant (P<0.05 model group vs. control and H₂ groups, P<0.01 model group vs. control and H₂ groups, respectively). The glucose tolerance test was performed to diagnose diabetes, insulin resistance and impaired beta cell function. As presented in Fig. 2J, following glucose intake blood glucose gradually increased, reached a peak at 30 min and subsequently decreased (P<0.05 model group vs. control and H₂ groups).}

**Determination of 3-NT and 8-OHdG in liver cells.** 3-NT, a biochemical marker of peroxynitrite, and 8-OHdG, a product of free radical oxidative damage to DNA, have been reported to be ameliorated by H₂ (25). The number of 3-NT- and 8-OHdG-positive cells were detected and are presented in Fig. 3A-D. The model group had more 3-NT-positive cells (Fig. 3A and C) and more 8-OHdG-positive cells (Fig. 3B and D) compared with the control and H₂ groups (P<0.05 model group vs. control and H₂ groups).

**TNF-α, IL-1β and CASP-3 in the liver.** The levels of the inflammatory cytokines TNF-α (Fig. 3E) and IL-1β (Fig. 3F) in the model group were significantly greater compared with the control and H₂ groups. CASP-3 activity in the model group was significantly greater compared with the control and H₂ groups (Fig. 3G; P<0.05 model group vs. control and H₂ groups).

**PPARα and PPARγ expression in the liver.** PPARα and PPARγ protein expression was detected using immunohistochemistry
As shown in Fig. 4A and C, PPARα protein expression was enhanced in the H2 group compared with the control and model groups. As shown in Fig. 4B and D, PPARγ protein expression was also increased in the H2 group compared with the control and model groups. These differences were statistically significant. The immunohistochemical results were confirmed by RT‑qPCR (Fig. 4E and F; P<0.05 model vs. H2 group).

**Discussion**

The present study demonstrated that H2‑rich saline significantly ameliorated NAFLD, as demonstrated by reduced serum ALT, TBIL, TC, TG, FBG and FINS levels, improved insulin sensitivity and glucose tolerance, and reduced hepatocyte apoptosis, inflammation and oxidative stress. The mechanism may possibly function by upregulating the expression of PPARα and PPARγ.

The key pathophysiological process associated with NAFLD is insulin resistance, which is common in T2DM. Insulin resistance within adipocytes causes lipolysis, which subsequently results in the generation of excess FFAs that are released into circulation and finally delivered to the liver. When the import and synthesis of FFAs exceeds the capacity of the liver to use them, hepatic steatosis occurs. Excessive FFAs are metabolized within the mitochondria, peroxisomes and microsomal system, which leads to lipid peroxidation, production of excess ROS and initiation of the inflammatory response. At present, the ‘two-hit’ theory of steatohepatitis pathogenesis, proposed by Day and James in 1998, is widely accepted (27). The theory separates the pathogenesis into two ‘hits’. The first hit is lipid accumulation due to insulin resistance and hyperlipidemia, which leaves the hepatocytes more vulnerable to injuries. Oxidative stress and the inflammatory response serve an important role in the second hit, which directly leads to hepatocyte injury. Therefore, NAFLD is a downstream effect of oxidative stress (28). Reduction of the overproduced ROS may theoretically improve NAFLD damage.

As an antioxidant, H2 has been reported to scavenge •OH and ONOO−, the two most toxic ROS in cells. In addition, H2 protects organs from tissue damage caused by severe oxidative stress induced by inflammation, intense exercise, cardiac infarction, cessation of blood flow and organ transplantation, among others (17). H2 is highly flammable, and it is not safe to preserve and use H2 for clinical practice and laboratory experiments. Therefore, H2 gas is often dissolved in normal saline under high pressure to produce H2‑rich saline, which exerts similar protective effects (29). Notably, it is safer and more convenient in practice.

The pathophysiological effects of DM are closely associated with oxidative stress (30), and several studies have examined the antidiabetic effects of H2. Kim and Kim (31) reported that electrolyzed reduced water with ROS scavenging

![Figure 2. Biochemical marker analysis, insulin tolerance and glucose tolerance tests. (A) Serum ALT and (B) TBIL levels were higher in the model group than in the control and H2 groups. ability had a potential effect on diabetic animals, significantly reducing blood glucose concentration and improving glucose tolerance. Kajiyama et al (12) demonstrated that in patients with T2DM, intake of H2-rich water was associated with significant decreases in the levels of modified low-density lipoprotein (LDL) cholesterol, small dense LDL and urinary 8-isoprostanes by 15.5, 5.7 and 6.6%, respectively, and concluded that supplementation with H2-rich water may have a beneficial role in the prevention and treatment of T2DM and insulin resistance. Kamimura et al (15) reported that H2 improved obesity and DM by inducing the expression of hepatic fibroblast growth factor 21 (FGF21) and improving energy metabolism in diabetic db/db mice, which is an important finding in the study of the mechanism of antioxidative effects of H2. The present study revealed that H2-rich saline ameliorated hepatic oxidative stress, which was demonstrated by a reduction in the levels of TNF-α, IL-1β, 3-NT and 8-OHdG in the liver.

Figure 3. Determination of 3-NT, 8-OHdG, TNF-α, IL-1β and CASP-3 levels. Representative immunohistochemical staining of (A) 3-NT and (B) 8-OHdG at x200 original magnification. Number of (C) 3-NT- and (D) 8-OHdG-positive cells. (E) TNF-α and (F) IL-1β content. (G) CASP-3 activity. *P<0.05 vs. control and H2 groups. 3-NT, 3-nitrotyrosine; 8-OHdG, 8-hydroxy-2′-deoxyguanine; CASP-3, caspase-3; H2, molecular hydrogen; IL-1β, interleukin-1 beta; TNF-α, tumor necrosis factor alpha.

The three PPAR subtypes (PPARα, PPARβ and PPARγ) belong to the nuclear receptor superfamily of transcription factors, and their response elements are located in the promoter region of FGF21. PPARα and PPARγ are two important upstream regulators of FGF21. PPARα is predominantly expressed in the liver and regulates lipid metabolism through activating the expression of various proteins, such as lipoprotein lipase and diacylglycerol acyltransferase. PPARγ is mainly found in adipose and hepatic tissue, and its activation serves a major role in increasing insulin sensitivity (32). The present study demonstrated that H2-rich saline significantly increased the expression levels of PPARα and PPARγ, and significantly improved glucose and lipid metabolism, as demonstrated by reduced serum levels of TC and TG, and improved insulin sensitivity and glucose tolerance. The present study also examined the serum levels of ALT and TBIL. Although H2 lowered the levels of ALT and TBIL, the difference was not statistically significant compared with
the model group. The present study attributed this result to the powerful compensatory capacity of the liver and the relatively short experimental time. It is expected that, if the experiment were conducted for a longer period of time and the damages to the liver went beyond the hepatic compensatory ability, liver function may be compromised.

Upon activation, PPARα and PPARγ synergistically inhibit fatty acid synthesis by regulating the expression of sterol regulatory element-binding protein-1c and its target gene fatty acid synthase (33). PPARα and PPARγ activation exerts anti-inflammatory effects on the liver by reducing hepatic steatosis, downregulating the expression of inflammatory genes and attenuating inflammation in adipose tissue (34). Furthermore, PPARα and PPARγ could regulate the production of free radicals by increasing the expression of superoxide dismutase and reducing NADPH oxidase activity (35,36).

In conclusion, the protective effects of H₂ on high-sugar and high-fat diet-induced NAFLD may be attributed to its direct antioxidative properties, as well as its activation of PPARα and PPARγ. With regards to PPAR activation, H₂-rich saline shares the same mechanism as rosiglitazone, which is a potent PPARγ receptor activator. Although further studies are required, H₂-rich saline may be considered a potential agent in the prevention and treatment of NAFLD.
