Abstract. Recent studies have indicated that progesterone (PROG) reduces the expression of inflammatory factors in brain tissue. The present study was designed to investigate whether PROG inhibits the inflammatory response and the infiltration of inflammatory cells in the brain. One hundred and seventy-six adult male Sprague-Dawley rats were randomly divided into four groups: a sham-operated (control) group, a permanent middle cerebral artery occlusion (pMCAO) group, a vehicle-treated group and a PROG-treated group. After pMCAO, the rats received an initial intraperitoneal injection of PROG (8 mg/kg) or vehicle at 1 h post-occlusion, followed by subcutaneous injections at 6, 24 and 48 h. The expression levels of intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1) and CD68 in the brain were measured by immunohistochemistry and Western blotting. The level of myeloperoxidase (MPO) activity was detected by spectrophotometry. The rats were sacrificed 72 h after surgery and isolated brain was sectioned into coronal slices and stained with 2,3,5-triphenyltetrazolium chloride (TTC). Western blotting and spectrophotometry revealed that the expression levels of ICAM-1, VCAM-1, CD68 and MPO were reduced in the brain tissue of PROG-treated rats. In addition, PROG-treated rats showed a substantial reduction in the infarct volume compared to vehicle controls. PROG effectively inhibited the inflammatory response and reduced the infiltration of leukocytes in the ischemic brain by inhibiting the expression of ICAM-1 and VCAM-1.

Introduction

Progesterone (PROG) is more than a gonadal hormone. Its neuroprotective effects have been documented in various nervous system diseases, including peripheral nerve injury, cerebral trauma, spinal cord injury and multiple sclerosis (1,2). The mechanisms underlying the neuroprotection of PROG against cerebral ischemia are not completely understood. It has been suggested that PROG is a pleiotropic agent that acts through a combination of intranuclear and membrane mechanisms (3). Studies have indicated that the multiple pathways by which PROG may exert its influence on experimental brain injury and stroke include γ-aminobutyric acid (GABA) inhibition and attenuation of excitatory amino acid responsiveness, amplification of the inhibition by adenosine of cerebral cortical neuronal activity, formation of new myelin sheaths, anti-apoptotic and antioxidant effects, reduction of brain edema and free radical scavenger activity (4-8). Our prior research also indicated that PROG has protective effects after cerebral ischemia in rats. PROG reduces the expression of inflammatory factors in brain tissue and lessens brain edema after infarction (9). Nevertheless, further research is necessary to determine whether PROG inhibits the inflammatory response and the infiltration of inflammatory cells in the brain after cerebral ischemia.

It has previously been shown that the inflammatory response, as represented by leukocyte infiltration, is an important change after stroke (10). The up-regulation of adhesion molecules is evoked by inflammatory cell factors, and the interaction between leukocytes and endothelial cells (ECs) plays a key role in inflammatory response. Inflammatory cell factors induce the up-regulation of intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1). ICAM-1 and VCAM-1 then cohere with the receptors located in leukocytes and induce the leukocytes to adhere to ECs. Subsequently, leukocytes emigrate and infiltrate the brain tissue. The up-regulation of ICAM-1 induces the infiltration of neutrophils, and the expression of VCAM-1 has a close relationship with monocyte/macrophage infiltration (11). Myeloperoxidase (MPO) activity is a dependable index to estimate the extent of infiltration by neutrophils. CD68 is a specific marker of macrophages.

In this study, we further explore the protective mechanism of progesterone as related to the inflammatory response in cerebral ischemia in rats. Since most cases of human stroke are caused by permanent occlusion of cerebral arteries, we used a permanent middle cerebral artery occlusion (pMCAO).
model in rats to study the in vivo inflammatory response after cerebral ischemia. The influence of PROG on the expression of ICAM-1, VCAM-1, MPO and CD68 was assessed. Our results support the efficacy of PROG treatment in inhibiting the inflammatory response and reducing leukocyte infiltration.

Materials and methods

Animal model. Animal experiments were conducted in accordance with the guidelines published in the NIH Guide for the Care and Use of Laboratory Animals, and all efforts were made to minimize animal suffering as well as the number of animals used. One hundred and seventy-six adult male Sprague-Dawley outbred rats (weight 250-280 g) were kept under a 12-h light-dark cycle and allowed free access to food and water. The rats were randomly divided into four groups: a sham-operated (control) group, an ischemic group, a vehicle-treated group and a PROG-treated group. Animals in each group were assigned to subgroups for immunohistochemical analysis (n=48), Western blotting (n=64), determination of MPO activity (n=32) and the measurement of infarct volume (n=32).

Rats were anesthetized with an intraperitoneal injection of 10% chloral hydrate (0.1 ml/100 g). Body temperature was monitored throughout surgery by a rectal probe and maintained at 37±0.5°C with a heating pad. Permanent cerebral ischemia was induced by occlusion of the left middle cerebral artery (MCA) using an intraluminal filament technique (12). The left common carotid artery, external carotid artery and internal carotid artery were isolated through a midline cervical skin incision performed under a microscope. A nylon monofilament (diameter 220 µm) coated with ‘thermomelting’ glue (length 4 mm; diameter 280 µm) was introduced through an arteriotomy performed on the external carotid artery and advanced into the internal carotid artery. Occlusion of the MCA was controlled by monitoring the cerebral blood flow in the MCA territory by laser Doppler flowmetry for 5 min after the insertion of the filament. Rats with less than 50% drop in blood flow were excluded from the study. Four died during surgery, and an additional 8 were excluded due to inadequate occlusion. After surgery, the wound was sutured and rats were returned to their cages and maintained at 25°C with free access to food and water. Sham-operated rats were subjected to the same surgical procedure, except that the filament was not advanced to occlude the MCA.

PROG was dissolved in 22.5% 2-hydroxypropyl-β-cyclodextrin, and the rats received an initial intraperitoneal injection of PROG (8 mg/kg) at 1 h post-occlusion followed by subcutaneous injections at 6, 24 and 48 h (13,14). In the vehicle-treated group, PROG was replaced by 2-hydroxypropyl-β-cyclodextrin in the same volume.

Immunohistochemistry. For the detection of ICAM-1 (n=8), VCAM-1 (n=8) and CD68 (n=8), the rats were sacrificed with an overdose (75 mg/kg) of sodium pentobarbital at 48 or 72 h after pMCAO. At the time of euthanasia, 8 rats in each group were anesthetized and transcardially perfused with ice-cold phosphate-buffered saline (PBS). The brains were carefully removed and placed in chilled saline, then sliced into coronal sections of 5-µm thickness starting at 3 mm posterior to the anterior pole. Sections were collected onto polyllysine-coated slides and allowed to dry, then de-waxed in 10 mM citrate buffer (pH 6) for 3 min, followed by blockage of non-specific binding by incubation in 0.1 M PBS containing 3% normal goat serum. Sections were subsequently incubated with primary antibodies (mouse monoclonal anti-ICAM-1, mouse monoclonal anti-VCAM-1 and mouse monoclonal anti-CD68; Santa Cruz) overnight at room temperature. Following extensive rinsing in 0.1 M PBS, the sections were re-incubated in biotinylated goat anti-mouse antibody (Santa Cruz) for 1 h at room temperature. Subsequent incubation in diaminobenzidine was performed for visualization of the reaction product. For negative controls, the primary antibody was omitted.

Protein isolation and immunoblotting. The rats in each group were sacrificed at 48 or 72 h post-occlusion with an overdose (75 mg/kg) of sodium pentobarbital. The brains were carefully removed and placed in chilled saline, and then total protein was isolated directly from the stratum corticale by lysing the cells into Laemmli buffer containing 2% SDS, 10% glycerol, 2% 2-mercaptoethanol and 0.002% bromophenol blue in 75 mM Tris-HCl. The samples were heated to 95°C for 10 min before being separated on 10% Tris/glycine/SDS acrylamide gels (Bio-Rad). The proteins were subsequently transblotted to polyvinylidene difluoride (PVDF) membranes (Minipore) and blocked for 2 h at room temperature in 5% dry milk. The immunoblots were incubated for 2 h at 37°C with mouse anti-ICAM-1, VCAM-1 and CD68 antibody (Santa Cruz). After three washes with TBS/0.05% Tween-20, the blots were incubated with a horseradish peroxidase-conjugated goat anti-mouse antibody (Santa Cruz) for 1 h at 37°C. Protein signaling was visualized using the SuperSignal West Pico Chemiluminescent Substrate (Pierce). Images of blots were captured with an Apple scanner and densitometric analysis of bands was performed using Scion software for Macintosh. Background values were subtracted and multiple blots were combined for statistical analysis. β-actin protein was visualized and detected as above.

MPO activity determination with tetramethylbenzidine (TMB). To measure MPO activity in ischemic brain hemispheres, the TMB assay (Sigma) was used, which detects the oxidation of 3,5,3′,5′-TMB by MPO through a change in absorbance at 655 nm. Brains were prepared as described above for Western blot analysis. Extracted protein (50 µl) was added to 950 µl of assay solution, and changes in absorbance were measured over 10 min. The units of activity were computed according to the formula: activity = (ΔOD x Vt x 4)/(E x ΔA x Vs), where OD is the change in absorbance, Vt is the total volume, Vs is the sample volume, E (extinction coefficient) = 3.9x10⁵ M⁻¹cm⁻¹, and ΔA is the change in time. Units of activity were normalized to 1 mg of protein.

Analysis of infarct volume. The rats were sacrificed 72 h post-occlusion with an overdose (75 mg/kg) of sodium pentobarbital. The brains were carefully removed and placed in chilled saline, and then sliced into 5 serial coronal sections of 2-mm thickness using a rat brain matrix starting at 3 mm posterior to the anterior pole. After sectioning, the slices were stained with 2% 2,3,5-triphenyltetrazolium chloride (TTC;
Sigma) in saline and kept for 15 min at 37°C in the dark. Stained sections were then fixed in 10% buffered formalin. Infarct volume (mm$^3$), as revealed by negative TTC stains indicating dehydrogenase-deficient tissue, was measured in each slice and summed using computerized planimetry (PC-based image tools software). The volume of infarction was calculated as 2 mm (thickness of the slice) x [sum of the infarction area in all brain slices (mm$^3$)].

Statistical analysis. Results are expressed as the mean ± SD. One-way ANOVA followed by the post-hoc least significant difference (LSD) test was used to ascertain any changes in ICAM-1, VCAM-1, CD68, MPO and infarct volume after pMCAO. P<0.05 was considered statistically significant.

Results

Effect of PROG on the expression of ICAM-1 after pMCAO in rats. The expression of ICAM-1 was detected with immunohistochemistry and Western blotting 48 h after occlusion (15). Fig. 1 illustrates the results of immunoreactivity for ICAM-1. Fig. 1A shows the expression of ICAM-1 at 48 h in the vehicle group. Fig. 1B shows the influence of PROG on ICAM-1 in the PROG group. Fig. 2 illustrates quantification of the effects of PROG on the expression of ICAM-1. Fig. 2A is a representative image of Western blotting. Fig. 2B shows the expression of ICAM-1 at 48 h in each group. The quantitative results revealed that ICAM-1 protein was present at very low levels in the control rats. Its expression was lower in the PROG group than in other groups. Statistical analysis showed that PROG administration significantly reduced the expression of ICAM-1 after pMCAO in the PROG-treated rats as compared to ischemic- and vehicle-treated rats (P<0.05).

Effect of PROG on the expression of VCAM-1 after pMCAO in rats. The expression of VCAM-1 reached its peak value at 48 h after cerebral ischemia, and then gradually decreased (16). Accordingly, the effects of stroke were determined in the absence and presence of PROG on the expression levels of this protein at 48 h after pMCAO using immunohistochemistry and Western blotting. Fig. 3 illustrates the results of staining for VCAM-1. Fig. 3A shows the expression of VCAM-1 at 48 h in vehicle-treated rats. Fig. 3B shows the influence of PROG on VCAM-1 in the PROG-treated rats at this time. From these
images it was not difficult to detect the differential expression of VCAM-1 in vehicle- and PROG-treated rats. Fig. 4 illustrates the effects of PROG on the expression of VCAM-1. Fig. 4A shows a representative Western blot. Fig. 4B shows the influence of PROG on VCAM-1 protein levels analyzed by Western blotting in the presence or absence of progesterone (8 mg/kg) 48 h after pMCAO. The numbers of each frame represent the ratio of VCAM-1/β-actin intensity (n=8) (PROG P<0.05 vs. ischemia and vehicle).

Effect of PROG on MPO activity after pMCAO in rats. The peak value of MPO was observed 48 h after cerebral ischemia in rats (17). Fig. 5 illustrates the effects of PROG on MPO activity. Compared to other groups, a significant increase in MPO activity was revealed in the ipsilateral hemisphere 48 h after pMCAO. However, at 48 h post-occlusion, the administration of PROG produced a significant reduction in MPO activity compared to ischemic- and vehicle-treated rats (P<0.05).

Effect of PROG on infarct volume after pMCAO. The cerebral infarction volume 72 h after pMCAO was significantly increased in ischemia and vehicle groups (Fig. 8). The infarction volume 72 h after pMCAO injury was significantly reduced for pMCAO-injured animals treated with PROG compared to vehicle controls (355 vs. 218 mm³).

Discussion

In the past decade, a growing number of studies have shown that exogenous administration of PROG or some of its metabolites can be successfully used to treat nervous system diseases, such as ischemic stroke. PROG has been shown to display neuroprotective properties following cerebral ischemia, decreasing lesion volume and improving functional recovery (14,19,13). Both cell survival and neuronal density are improved by acute or chronic PROG treatment in male (19) and female (20) animals. After brain ischemia, PROG stimulates the protective pathways that suppress the inflam-
matory response (9,7,21,22) by reducing the expression of proinflammatory cytokines and decreasing post-stroke edema (9,7). However, further study is necessary to clarify whether PROG inhibits the inflammatory response and the infiltration of inflammatory cells in the brain after cerebral ischemia.

The present study was conducted to examine the inhibitory effects of PROG on the expression of adhesion molecules after pMCAO. The results showed that simultaneous administration of 2-hydroxypropyl-β-cyclodextrin with PROG reduced the expression of ICAM-1 and VCAM-1 after stroke.

Cell adhesion molecules (CAMs) have attracted considerable attention in the study of cerebral ischemia injury (10,23,24). These adhesion molecules play an important role during stroke. CAMs are a type of glycoprotein that mediate cell adhesion to other cells and to the extracellular matrix. Such adhesion is very important in inflammation and immune response. For example, one important step in inflammation is the extravasation of leukocytes, which involves adhesion to vascular endothelial cells. Leukocyte rolling, binding with vascular endothelial cells and migration in between endothelial cells requires the participation of CAMs. The initiating stage of adhesion is mediated by selectin. The CD11/CD18 compound and ICAM-1 then form a tighter combination, which ultimately allows leukocyte infiltration of the extracellular milieu by allowing these cells to pass through the endothelium (25). The infiltration of neutrophils increases the following up-regulation of ICAM-1 after cerebral ischemia in mice. ICAM-1 knockout mice are insensitive to cerebral ischemic reperfusion injury. Compared to wild-type mice, ICAM-1 knockout mice display a 37-fold decrease in cerebral infarction volume, a 31-fold increase in cerebral blood flow in the infarction hemisphere, and a 35% increase in the degree of infarction 24 h after focal ischemia. Inhibiting the expression of ICAM-1 or CD18 limits the aggregation of neutrophils in the ischemic region as well as the infarction volume. PROG also improves microcirculation disturbances and protects against cerebral ischemia (11). VCAM-1 resides in the cell membranes of vascular endothelial cells. Its expression increases when stimulated by inflammatory factors. VCAM-1 binds predominantly with very late antigen-4 (VLA-4). VLA-4 resides on the cell surfaces of monocytes and eosinophils. VCAM-1 participates in the infiltration of mononuclear phagocytes.

Our study indicated that PROG also inhibited the infiltration of neutrophils and macrophages in brain tissue. We analyzed MPO activity and CD68 expression, which reflects the infiltration of neutrophils and macrophages.

MPO is a commonly used marker of neutrophils. This protein is found in the azurophil granule. MPO catalyzes the production of oxidizing material, induces oxidative stress and exacerbates oxidative tissue injury. MPO activity can be used to reflect neutrophil infiltration. CD68, a 110-kDa transmembrane glycoprotein that is highly expressed by monocytes and tissue macrophages, is a member of the lysosomal/endosomal-associated membrane glycoprotein (LAMP) family, and also of the scavenger receptor family. Scavenger receptors typically function to clear cellular debris, promote phagocytosis and mediate the recruitment and activation of macrophages. The expression of CD68 increases when macrophages are activated. Therefore, CD68 is a marker for macrophages (26).

We found that neutrophils were the most important inflammatory cells during the period immediately following ischemia. Neutrophils display phio-eosin grains in the cytoplasm and their nuclei are segmented. Neutrophils pass through vascular endothelial cells 12 h after MCAO. There are abundant neutrophils in brain parenchymatous tissue 12-72 h after MCAO (27), as supported by our observations.

Macrophages also participate in the inflammatory response after stroke. The cytoplasm of each macrophage is cysteine and the nucleus is ovoid in shape. There are two kinds of macrophages in the brain after ischemia: activated microglia and mononuclear phagocytes. A previous study (28) indicated that the first macrophages to be activated are the microglia, while mononuclear phagocytes are activated later. Macrophages clearly containing cellular remnants release interleukin-1β and tumor necrosis factor-α. These macrophages dispose of cellular remnants and repair injury, but also cause secondary lesions.
In this study, we discovered that PROG treatment significantly inhibited the inflammatory response, and reduced the infiltration of leukocytes and the cerebral infarction volume after experimental stroke. These findings support the development of new therapeutic approaches for stroke and other nervous system diseases.
