Abstract. Early diagnosis of acute mesenteric ischemia (AMI) remains very difficult, partly due to the fact that useful markers of early small bowel ischemia have not yet been identified. Thus, in this study, we aimed to evaluate the levels of serum intracellular enzymes in the tissues and organs in a controlled animal model of mesenteric intestinal ischemia. Forty-eight New Zealand rabbits were divided into 4 groups including the control, artery ligation, vein ligation, and both artery and vein ligation groups. Plasma samples were obtained at 0-, 1-, 3-, 6- and 9-h time-points and enzyme levels were determined. The bowel color and vitality were observed at the same time. The bowel showed an appearance of infarction after a period of ischemia in the animals. Six and 9 h after superior mesenteric artery ischemia, alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels increased significantly. However, after 3 h of superior mesenteric venous (SMV) ligation, γ-glutamyl transpeptidase levels in the blood were considerably higher compared to the control group. Six hours after SMV ischemia, ALT, AST, alkaline phosphatase and lactate dehydrogenase levels were significantly elevated compared to those pre-ligation. Serum enzyme levels during intestinal ischemia are not able to provide sufficient information as regards the extent and reversibility of intestinal ischemia, although, they may be able to reflect the presence of injury.

Introduction

Acute mesenteric ischemia (AMI) is a life-threatening condition characterized by the sudden occlusion of mesenteric arteries followed by impairment of intestinal blood flow. It is classified as acute mesenteric arterial embolism and thrombosis, mesenteric venous thrombosis, and nonocclusive mesenteric ischemia (1-3). Early diagnosis of AMI remains very difficult, primarily because the early clinical symptoms of this disease are non-specific and initially subtle. Therefore, diagnosis is considerably delayed, by which stage both the patient and the intestine are severely compromised. Despite the progress in the diagnosis and treatment of AMI over the past four decades, it still has a poor prognosis with an in-hospital mortality rate of 59-93% (4-6).

To date, there are no reliable and easy-to-use laboratory markers available for the accurate and early diagnosis of ischemia. Although various markers for AMI have been investigated, most of them have shown low sensitivity and are not capable to be used in clinical practice.

In this study, we aimed to determine whether plasma enzyme levels would become elevated in rabbit models of AMI and whether these elevations could be used as a predictor for AMI.

Materials and methods

Animal model. Forty-eight male and female New Zealand white rabbits (2.5-3 kg body weight) were assigned into 4 groups (12 in each). Animals were handled with the approval and according to the rules of the animal research committee. All experimental procedures were performed in well equipped animal facilities. The animals were divided into the 4 following groups: group I (controls), animals underwent sham laparotomy with exposure of the superior mesenteric artery (SMA) and superior mesenteric venous (SMV) after appropriate anesthesia; group II, SMA and identified collaterals were ligated; group III, SMV and identified collaterals were ligated; and group IV, both SMA and SMV were ligated.

Surgical procedure. The animals were anesthetized with 3% barbital, 30-35 mg/intravenous injections. An internal femoral vein intravenous catheter was then placed so that blood samples could be taken from the animals. The experimental animals underwent a standard midline laparotomy. The small intestine was reflected to the left of the abdominal incision and then the SMA and SMV were identified. Mesenteric ischemia was confirmed when the mesenteric pulsation was lost and the intestine became pale (Fig. 1). After SMA or/and SMV ligation, heparinized blood samples were obtained from the femoral vein at 0- (before ligation), 1-, 3-, 6- and 9-h time-points. At each time-point, plasma was separated immediately and stored at -20°C until analysis. Plasma aspartate aminotransferase (AST), alanine aminotransferase (ALT), and γ-glutamyl transpeptidase (γ-GTP) levels were determined.
Figure 1. Surgical procedure using the animal model. (A) Superior mesenteric artery (SMA) ligation. (Black arrow, SMA). (B) Superior mesenteric venous (SMV) ligation. (Black arrow, SMV). (C) SMA and SMV ligation. (Black arrow, SMA and SMV).

Figure 2. Bowel of the rabbits of the superior mesenteric artery (SMA) ligation group. (A) One hour after SMA ligation, the bowel became pale and dilated. (B) Three hours after ligation, the color of the bowel changed to grey and focal necrosis of the bowel could be seen. (C) Six hours after SMA ligation, extensive patchy necrosis and dilation throughout the small bowel with free hemorrhagic intraperitoneal fluid was evident. (D) Nine hours after SMA ligation, the ischemic small bowel became black in color due to hemorrhage in the infarcted bowel.

Figure 3. Bowel of the rabbits in the superior mesenteric venous (SMV) ligation group. (A) One hour after SMV ligation, changes in the bowel were evident, similar to those seen after 3 h in the superior mesenteric artery (SMA) ligation group. Necrosis and hemorrhage of the small bowel could be seen. (B) Three hours after SMV ligation, the bowel changed to a black color and extensive hemorrhagic infarction of the bowel was found. (C) Six hours after SMV ligation, the appearance of vitality was lost and most of the animals died.
transferase (ALT), alkaline phosphatase (ALP), γ-glutamyl transpeptidase (γ-GT), creatine kinase (CK), creatine kinase-MB (CK-MB) and lactate dehydrogenase (LDH) levels were measured in a Technicon RA-XT autoanalyzer using commercially available spectrophotometric kits (7).

Data analysis. The results were presented as the means ± SD and used for statistical analysis using t-tests. A P-value of <0.05 was considered statistically significant.

Results

All control animals were found to have a normal-appearing bowel, while all the SMA or/and SMV ligation animals had an obvious abnormal-appearing bowel. The bowel became pale and changed to a grey color 5 to 10 min after vessel ligation. Three hours after ligation, focal necrosis of the small bowel was evident. Six hours after ligation, the animals had extensive patchy necrosis and dilation throughout the small bowel with free hemorrhagic intraperitoneal fluid. Nine hours after ligation, the small bowel was completely dilated and had changed to a black color. Most of the animals died 9 h after vessels ligation (Figs. 2 and 3).

In group I all the animals survived. In group II all the animals survived for up to 9 h. The plasma enzyme levels are shown in Table I. Six and 9 h after SMA ischemia, ALT and AST levels reached 117 and 235 IU, respectively. Significant differences were found between pre-ligation and 6 (P<0.05) and 9 h after ligation (P<0.01) (Fig. 4). In group III, all the animals died within 6 h. Three hours after SMV ligation, γ-GT levels in the blood reached 12 IU, which was considerably higher compared to the controls (mean value, 5.5 IU) (Fig. 5A). Six hours after SMV ischemia, ALT, AST, ALP and LDH levels were significantly elevated compared to those pre-ligation (P<0.05 and 0.01) (Fig. 5B and C). In group IV, the plasma enzyme levels increased after vessel ligation, but no significant difference was observed (Table III).

Discussion

AMI is a potentially fatal vascular emergency which comprises a group of pathophysiological processes that have a common end-point, bowel necrosis. In addition, AMI can be characterized by an initial discrepancy between severe abdominal pain and minimal clinical findings. Moreover, many of the patients who develop AMI suffer from other severe medical conditions, such as peritonitis, ileus, pancreatitis and gastrointestinal bleeding at the same time, which make the symptoms less reliable (8,9). Due to the non-specific clinical symptoms and presentations, early diagnosis and intervention of AMI are remain very difficult.

Previous studies have attempted to find simple laboratory tests which might identify AMI before bowel infarction and irreversible changes have occurred. Most of these studies have focused on potential biological markers of gut ischemia and injury, including measuring various intracellular enzymes released by the ischemic bowel, such as aminotransferase, LDH, D(-)-lactate, tyrosin, creatine phosphokinase and alcohol dehydrogenase (10-14). Unfortunately, all these markers have a low specificity and can not be used in clinical practice. In other similar studies, serum AST, ALP, LDH and CK levels were investigated in order to determine intestinal necrosis resulting from ischemia (15,16). In those studies, significant increases in peripheral enzyme levels were generally found after ≥3 h periods of ischemia. In this study, we found that ALT and AST levels increased after >6 h in the SMA ligation group, while ALT, AST, ALP and LDH levels increased after 6 h in the SMV ligation group. Although ALP is considered as a diagnostic parameter of ischemic bowel, it was not found

to increase earlier. CK-MB isoenzyme has been reported to be a more sensitive indicator of bowel necrosis than the intestinal isoenzyme of ALP (13). However, increases of CK and CK-MB were not found at any stage in our study. Additionally, a significant increase in γ-GT levels was also found after 3 h of ischemia, earlier than other enzymes, in the SMV ligation rabbits. We presume that the increase in γ-GT levels may be caused by hypoperfusion and injury of the liver.

There are several reasons why our results differ from those of previous studies. Firstly, complete or incomplete ischemia and the presence of venous or lymphatic drainage from the damaged tissue may affect blood enzyme levels during ischemia. Secondly, due to the massive metabolic capacity of the liver, the concentrations of these substances in the peripheral blood remain fairly stable and unchanged unless serious or irreversible damage has occurred. In addition, different experimental animals used in these studies may also play a role.

Hepatic hypoperfusion and acute hepatic damage after ischemia were also reported. It was shown that after 2 h of intestinal ischemia, the ALT level increased up to four times the normal level (17). In this study, plasma ALT, AST and γ-GT levels increased significantly in the SMV ligation models, possibly due to hepatic hypoperfusion and damage to the liver during the study period.

In conclusion, as has also previously been shown, the increased enzyme levels cannot provide sufficient information as regards the extent and reversibility of intestinal injury, but only to reflect the presence of the injury (18). Increase in serum enzyme levels during intestinal ischemia may also depend on the animal models used. The significant increases in serum

enzyme levels are usually late signs and are frequently associated with bowel infarction. Thus, early diagnosis of AMI can only be made by a physical examination, clinical presentation and laboratory tests, using the help of modern diagnostic techniques, such as CT, MRI and angiography.
