Abstract. The aim of the present study was to evaluate the efficacy and safety of pegylated liposomal doxorubicin (PLD) in patients with Müllerian carcinoma treated at our hospital. Nineteen patients with platinum-resistant Müllerian carcinoma were treated with intravenous PLD 50 mg/m$^2$ every 4 weeks. Tumor response was assessed by MRI following every 2-3 cycles of treatment. The severity of adverse events was assessed according to the Common Terminology Criteria for Adverse Events (v3.0). The best overall responses in the 19 patients were identified as 5 partial responses (PR), 6 stable diseases (SD) and 8 progressive diseases (PD). Response rate was 26.3%. The proportion of patients with CR, PR or SD was 57.9%. The median time to progression was 188.0 days. The median survival time was 381.0 days. Toxicity grades were identified as one grade III hand-foot syndrome, two grade III neutropenia, one grade IV hand-foot syndrome, one grade IV stomatitis and one grade IV neutropenia. The present study confirmed that PLD is an effective drug when administered as a salvage therapy for the treatment of Müllerian carcinoma and is associated with a reduced toxicity profile compared with current therapeutic options.

Introduction

Epithelial ovarian carcinoma is one of the most common gynecological malignancies and the fifth most frequent cause of cancer mortality in females (1). Epithelial ovarian and peritoneal carcinomas and primary carcinoma of the Fallopian tube are all classified as Müllerian carcinomas. These diseases exhibit a number of similarities and are often treated using similar therapeutic protocols. Advanced epithelial ovarian cancer is highly chemosensitive and 70-80% of patients initially respond to platinum-based chemotherapy. However, in 60-80% of cases these tumors increase in severity and treatment with second-line agents becomes necessary (2,3). Tumors which do not progress in severity until more than 6 months following completion of first-line platinum-based treatment are considered likely to remain platinum-sensitive and generally receive a chemotherapy regimen containing a platinum agent. However, tumors associated with severe progression in less than 6 months following completion of the first-line chemotherapy are considered to be platinum-resistant (4). Secondary treatments currently induce a response in 14-40% of patients and these responses are generally of short duration (5). This results in rapid disease recurrence following discontinuation of therapy. At present, it is considered extremely difficult to cure recurrent ovarian cancer and existing therapies are considered suitable for increasing the duration of survival and palliative therapy only. Consequently, suitable therapeutic agents for the treatment of this disease are required to demonstrate efficacy and low toxicity.

Doxorubicin has a wide spectrum of activities in human tumors and is considered to be suitable as an active agent for the treatment of advanced ovarian cancer (6-8). However, use of this anthracycline agent is limited by side-effects, including gastrointestinal toxicity, myelosuppression and cumulative cardiac damage (9). Pegylated liposomal doxorubicin (PLD) is a unique formulation of conventional doxorubicin that avoids phagocytosis. This results in prolonged circulation time with drug retention in liposomes and selective accumulation in the tumor vascular bed following extravasation through the leaky tumor vasculature (10,11). PLD was designed specifically to enhance the efficacy of doxorubicin and reduce its toxicities, including myelosuppression, alopecia and cardiotoxicity.

The aim of the present study was to evaluate the effects of PLD in a non-trial setting to evaluate the efficacy and safety of the treatment.
Materials and methods

Patients. The present study was retrospective and aimed to evaluate the efficacy and safety of PLD in Japanese patients with ovarian carcinoma previously treated with platinum-based chemotherapy at our hospital. The primary endpoint of the study was determination of best overall response. The secondary endpoint included analysis of adverse events and drug reactions and duration of response. The study included 18 patients with epithelial ovarian carcinoma and 1 with peritoneal carcinoma and was approved by the Ethics Committee of Osaka City University. All patients were identified as platinum-resistant. Written informed consent was provided by all patients prior to treatment with PLD at our hospital between July 2009 and March 2011.

Treatment and clinical course analysis. Patients were treated with PLD at a dose of 50 mg/m² every 4 weeks, which was delivered in 250 ml of 5% dextrose solution and administered as an intravenous infusion over 1 h. All patients received standard premedication of intravenous dexamethasone (10 mg) and ramosetron hydrochloride (0.3 mg). Prior to each PLD cycle, toxicity evaluations were performed. Tumor response was reassessed by MRI following every 2-3 cycles of treatment in all cases. Tumor response evaluation was performed according to the RECIST guidelines. The severity of adverse events was assessed according to the Common Terminology Criteria for Adverse Events (v3.0). Subsequent courses of chemotherapy were planned every 28 days pending an absolute neutrophil count (ANC) of 1,500 cells/ml and resolution of ≥grade II nonhematological toxicity. In the event of persistent neutropenia (ANC <1,500 cells/ml) or ≥grade II nonhematological toxicity, the therapy was delayed and the patients were reevaluated weekly using these criteria for reinstitution of therapy. PLD dose reductions of 10 mg/m² were instituted in the event of grade III or IV nonhematological toxicity.

Statistical analysis. Probabilities of survival and progression-free survival were analyzed using the Kaplan-Meier method (12). StatView 5.0 (Abacus Concepts, Berklely, CA, USA) was used for statistical analysis. P<0.05 was considered to indicate a statistically significant difference.

Results

Patient characteristics. The demographics and baseline characteristics of the patients are presented in Table I. Between July 2009 and March 2011, 19 patients were treated with PLD. The median age of the patients was 54.8 years (range, 39-75 years). Among the 19 patients, 18 had epithelial ovarian carcinoma and 1 had peritoneal carcinoma. Histologically, 11 patients had serous adenocarcinoma, 3 had clear cell adenocarcinoma, 2 had mucinous adenocarcinoma, 2 had poorly differentiated adenocarcinoma and 1 had endometrioid adenocarcinoma. The most common FIGO stage was III. Prior to treatment with PLD, 2 patients received one chemotherapeutic regimen, 11 patients received two regimens, 4 patients received three regimens and 2 patients received four regimens.

Tumor characteristics. The antitumor effects (best overall responses) and response rates are presented in Table II. The best overall responses in the 19 patients were 5 partial responses (PR), 6 stable diseases (SD) and 8 progressive diseases (PD). The response rate was 26.3%. The proportion of patients with complete response (CR), PR or SD was 57.9% (11/19 patients).

The Kaplan-Meier curve for time to progression is demonstrated in Fig. 1. Median time to progression was 188.0 days. The Kaplan-Meier curve for overall survival is shown in Fig. 2. Median survival time was 381.0 days.

Table III provides a summary of the grade III and IV toxicities. The toxicities were grade III hand-foot syndrome (HFS) in 1 patient (5.3%), grade IV HFS in 1 (5.3%), grade IV stomatitis in 1 (5.3%), grade III neutropenia in 2 (10.5%) and...
The common toxicities identified in the present study were hematological toxicities, HFS, and stomatitis. Grade III-IV HFS was observed in 2 patients (10.5%), grade IV stomatitis was observed in 1 (5.3%) and grade III-IV neutropenia was observed in 3 (15.8%). A previous phase II clinical trial in Japan identified that 16.2, 8.1 and 67.6% of patients experienced grade III-IV HFS, stomatitis and neutropenia, respectively (19). Only 1 case of grade IV stomatitis required therapy delay and a dose reduction. However, all patients were able to receive PLD continually. Side-effects previously associated with doxorubicin, including allergic reactions and cardiotoxicity, were not identified, indicating that PLD is a well-tolerated agent.

In conclusion, recurrent ovarian cancer is extremely difficult to cure, with current therapies functioning only to lengthen the duration of survival and palliative therapy. At present, the main aim of recurrent epithelial ovarian carcinoma management is to reduce harm. Additional aims of therapy must include the alleviation of cancer-related symptoms and extension of symptom-free, progression-free and overall survival where possible. Suitable agents must not only be effective but should also be associated with low toxicities. The present study confirms that PLD is suitable for use in salvage therapy of Müllerian carcinoma and has a reduced toxicity profile compared with current therapeutic options.
